Abstract. A pseudotachylyte bounded by a carbonate-matrix implosion breccia was found at a fossilized out-of-sequence thrust in the Shimanto accretionary complex, Japan. This occurrence resulted from the following events: first implosion of host rock due to interstitial fluid pressure increase and asymmetric fracturing; second, Ca-Fe-Mg carbonate precipitation; and third, frictional melting. The rock-record suggests that these events took place in a single seismogenic slip event. Resulting from abrupt drop in fluid pressure after implosion, hydro-fracturing and fluid escape, recovered high effective friction promoted melting during fault movement. Coexistence of fluid implosion breccia and pseudotachylyte has never been reported from continental pseudotachylytes, but might be characteristic from hydrous seismogenic faults in subduction zones.

1 Introduction

Pseudotachylyte formed by frictional melting has been the only convincing geologic evidence of rapid slip along seismogenic faults (e.g. Spray, 1992, Cowan, 1999). Under hydrous conditions, however, frictional melting has been considered to be prevented and other mechanisms, such as thermal pressurization of pore fluid (Sibson, 1973, 1975; Lachenbruch, 1980; Mase and Smith, 1987), acoustic fluidization (Melosh, 1996; Otsuki et al., 2003), or elastohydrodynamic lubrication (Brodsky and Kanamori, 2001), were thought to contribute to the dynamic weakening for unstable slip of earthquakes. In the seismogenic subduction zone, therefore, the predominant mechanisms have been implicitly considered to be fluid-induced weakening without frictional

melting because the subduction zone is fundamentally rich in water under relatively low temperature conditions.

Recently geological evidence of frictional melting has been increasingly reported from several ancient accretionary prisms uplifted from seismogenic depths of subduction zones (Ikesawa et al., 2003; Austheim and Andersen, 2004; Kitamura et al., 2005; Rowe et al., 2005; Mukoyoshi et al., 2006) but the relationship between the conflicting mechanisms; e.g. thermal pressurization of fluid and frictional melting is still unclear.

We found a new exposure of pseudotachylyte from a fossilized out-of-sequence thrust (OOST) in an exposed accretionary prism. This unique fault, not previously reported, is associated with an implosion breccia embedded in a precipitated carbonate matrix, suggesting that both thermal pressurization of fluid/hydrofracturing (Sibson, 1986) and frictional melting operated. In this paper, we first describe the fault rock and then discuss dynamic weakening process in the hydrous seismogenic fault.

2 Geologic setting

The Nobeoka thrust is an OOST bounding the northern and southern Shimanto Belts of the Cretaceous-Tertiary accretionary complex in Kyushu, southwest Japan (Fig. 1). The thrust is traceable for more than 300 km in the Shimanto Belt, parallel to the modern Nankai Trough.

Hanging-wall rocks of the thrust are composed of the Eocene Kitagawa Group of plastically deformed meta-shales and meta-sandstones. Foot-wall strata of the Eocene Hyuga Group are composed of shale matrix mélange with sandstone and basaltic blocks deformed mainly by a brittle mechanism. The deformation fabrics of these rocks are consistent with the sense of shear along the Nobeoka Thrust (Kondo et al., 2005). Geo-thermometry using vitrinite reflectance indicates that the Kitagawa and the Hyuga Groups experienced heating

up to maximum temperatures of about 320° and about 250° , respectively (Kondo et al., 2005). The Nobeoka thrust is characterized by a cataclastic fault core about 20 cm thick and by a brittle damage zone whose thickness is several tens of meters in the hanging-wall and about 100 m in the foot-wall. Ubiquitous subsidiary shear, whose orientation is parallel to that of the fault core of the Nobeoka thrust, are present in the damaged zone.

Kondo et al. (2005) pointed out that the Nobeoka Thrust was formed at seismogenic depths from the viewpoint of thermal models (e.g. Hyndman et al., 1997), in comparison with the OOST in the modern Nankai Trough (Park et al., 2002) and on the basis of cataclastic deformation with fluid flow although direct evidence such as pseudotachylite was not documented.

3 Asymmetric crack, implosion breccia and pseudotachylite

This unique fault rock was found from one of the subsidiary faults in the hanging wall about 10 m above the fault core of the Nobeoka thrust. The subsidiary fault is composed of two different parts along the fault surface: narrow, planar slip sections and wider zones along dilation jogs (Fig. 2A). The planar slip section shows two-stages of deformation as documented by the cross-cutting relationship, first by asymmetric extensional cracking, especially in the foot-wall, then by frictional melting. The dilation jogs apparently deformed by a single stage of implosion.

3.1 Implosion breccia of the boundary of the fault core, dilation jog and asymmetric extensional cracks

The fault core of the slip sections is bounded mainly by host rocks but partly by a cataclasite-like zone (Fig. 2D). The zone is bounded by a clear wavy wall from the host in the hanging wall and connected with cracks in the foot-wall (Figs. 2A and 2B).

The cataclasite-like zone is composed of breccias of the host rock made of grains of various size embedded in a dark matrix. EPMA (Electron Probe Micro-Analyzer) and XRD (X-ray Diffractometer) analyses give evidence that the matrix is made of precipitated Ca-Fe-Mg carbonates that are not found in the host rocks.

The breccia is also present in cracks in the foot-wall and the dilation jogs (Figs. 2A–2D). The shapes of the cracks are irregular, but orientations $\sim 30\text{--}40^\circ$ clockwise from the slip plane dominate. Fewer cracks are oriented parallel to the foliation of the host rocks (Figs. 2A and 2F). Thicknesses of the crack veins decrease with distance from the fault core (Figs. 2A and 2B). The lengths of the jogs are several tens of cm parallel to the slip direction (Fig. 2A), which is minimum indication of displacement along the fault.

The dilation jogs are filled by Ca-Fe-Mg carbonates that encircle breccias of host rocks (Figs. 2A and 2D). The component is similar to that of the implosion breccia observed in the slip part as described. Crystal sizes of carbonates are smaller than a few tens of μm (Fig. 3B).

3.2 Pseudotachylite

1 mm thick fault core along the slip part of the fault is composed mainly of materials that are translucent under the optical microscope (Fig. 2E). Chemical analysis by EPMA (Fig. 4A), crystallographic analysis by XRD (Fig. 4B) and TEM (Transmission Electron Micrograph) analysis (Fig. 3H) revealed that the pseudotachylite is now composed dominantly of palygorskite ($\text{Al}_2\text{Fe}\square_2\text{Si}_8\text{O}_{20}(\text{OH})_2(\text{OH}_2)_4\text{Mg}(\text{H}_2\text{O})_4$) and amorphous materials. The sign (\square) in the chemical formula means vacancy in the crystal structure. Survival fragments are quartz, calcite and illite-chlorite aggregates. Palygorskite is never found in the host rocks (Fig. 4B).

SEM-BSI (Scanning Electron Microscope- Back Scatter Image) enabled the observation of various melt-and-quench related features of pseudotachylite. The pseudotachylite constitutes the “upper and lower domains” in Fig. 3A. The “upper domain” is composed of homogeneous matrix containing a few fragments of quartz, calcite and illite-chlorite aggregates. Margins of the fragments are plastically deformed and show embayment and frame texture due to the melting (Figs. 3D and 3E). Fe-rich micro-spherules with diameter of several μm are distributed along the hanging-wall of the upper domain (Figs. 3C and 3H). The size of the spherules becomes larger toward the upper margin (Fig. 3C). Their crystallization might have resulted from oxidation of Fe in melt during the melt-quenching event (Nakamura et al., 2002).

Elongated voids whose size is a few to several μm are recognized in the upper domain (Figs. 3A and 3E). Elongated voids show internal tiny vesicles and globular material surfaces (Fig. 3G) similar to features described by Kennedy and Spray (1992). Stretched icicle-like features are observed

Fig. 2. Sketch and photographs of the studied fault. (A) sketch of the fault. Outcrops are oblique to the slip direction (SSE). Note that the fault is composed of two parts: sharp planar sections and dilation jogs. (B) and (C) Outcrop of slipped part. (D) Outcrop of dilation jog. (E) Photomicrograph of the slipped part. Note that translucent fault core is bounded by cataclasite-like breccia in the dark carbonate matrix. (F) Orientation frequency diagram of cracks filled by carbonate together with lower-hemisphere stereograph of foliations. The orientation is measured on thin sections in parallel to the slip direction and perpendicular to the fault plane, foliations of host-rock phyllite and the cracks. Note that predominant orientations are $30^\circ \sim 40^\circ$ clockwise from the slipped plane. Other large cracks are controlled by foliation as shown in (A). (G) Stereographic projection (lower hemisphere) of the orientation of the step walls of the dilation jog, fault plane and slip. Note that the orientation of the step wall is perpendicular to the slip direction.

within the cracks (Fig. 3F). Cooling cracks enveloping partially molten grains are also well displayed (Fig. 3D).

The lower domain consists dominantly of ultracataclastic aggregates (Fig. 3A). Margins of fragments mostly retain their original shapes although partially molten, especially in the illite/chlorite aggregates. Larger fragments are concentrated in the upper part of the lower domain and floated in the upper molten domain (Fig. 3A). Such aspects resemble grain flow textures of sediments.

The pseudotachylite, especially the completely molten upper domain, pinches out as the dilation jog filled by implosion breccia is approached (Fig. 2D).

4 Discussion

Here we discuss the characteristic aspects of the fault described above and its significance for the mechanics of seismogenic faults.

4.1 A single slip fault

The two staged deformation in the slip part show that fracturing with fluid implosion occurred first, followed by frictional melting. One can explain that there was a long hiatus between the two events and accidental slip along the same fracture. If this was the case, slip repetition should be recorded

in the fault core (e.g. layered pseudotachylite, Otsuki et al., 2003) and part of the dilation jog should be cut by the fault. The internal texture of pseudotachylite, however, does not represent such a repetition, but rather represents a simple separation of upper and lower domains as described. The separation appears to be a gravitational effect because inverse grading texture of fragments resembles grain flow textures which are commonly observed in sediments. Thus, the fluid implosion with fracturing might have occurred early, with the frictional melting occurring later during a single slip event. The planar part fades into the dilation jog that is filled only by implosion breccia. This occurrence suggests that the fracturing was concentrated at the jog during slip propagation. Thus, the observed fault suggests a single slip event with several tens of cm displacement.

4.2 Asymmetric cracking with implosion breccia

Theoretically predicted cracking in the “process and damage” zones (Cowie and Scholz, 1992; Scholz et al., 1993) is observed in many natural examples (e.g. Vermilye and Scholz, 1998; Kim et al., 2004). They show that extensional Mode I fractures develop in parallel to the transient σ_1 in the vicinity of the fault tip, and/or around jogs, which progress to the damaged zone as a result of slip propagation (e.g. Kim et al., 2004). Asymmetric development, the angle between crack and fault surface, and the change in crack-width that

we observed are quite consistent with those of the Mode I fractures in the damage zone (Kim et al., 2004).

A difference from commonly observed Mode I fractures is that the cracks are filled with carbonate and connected with the dilatant jog. Such an occurrence suggests that the Mode I rupture is not only due to transient stress concentration around the fault propagating tip or jog but also due to hydro-fracturing, that would have taken place due to a large fluid pressure gradient between the pore fluid in preceding cracks in the process zone or jog, and the damage zone (Billi et al., 2003). Such a large pressure difference between the source and sink collapses the wall and produces the implosion breccia (Sibson, 1986).

4.3 Ca-Fe-Mg carbonate precipitation for the matrix of implosion breccia

Crack-filling veins and matrices of implosion breccia are characteristically composed of Ca-Fe-Mg carbonates as de-

scribed. The matrix-supported texture suggests rapid precipitation of carbonates because, if precipitation did not occur quickly, the grain structure would have collapsed, leading to a grain-supported structure. The mean diameter of matrix carbonate crystals is less than a few tens of μm . Such tiny crystal aggregates are different from ordinary vein-filling carbonates and suggestive of abrupt precipitation, although the exact precipitation rate is unknown.

Carbonate solubility is controlled by pH, KH and CO_2 concentration of the fluid, which depend on pressure-temperature conditions (Holland, 1967; Holland and Martin, 1979). Dynamic formation of extensional cracks and jogs results in adiabatic fluid expansion and sudden fluid pressure drop, which abruptly reduces the solubility of carbonates and lead to precipitation of the tiny crystals.

Fig. 4. (A) EPMA elements mapping of the pseudotachylite, implosion breccia, and host rock. Note that Si, Fe, Mg and Al characterize the pseudotachylite. Fe, Mg and Ca are found from the matrix of implosion breccia. Location for these maps is shown in Fig. 2E. (B) XRD analyses for the pseudotachylite, implosion breccia, and host rock. Note the broad band ranging from 12° to 42° of the pseudotachylite, which coincides with that of glassy material reported by (Lin and Shimamoto, 1998). Palygorskite and the broad band never presents in parts of implosion breccia and host rock, and calcite and ankerite are not found in the host rocks.

4.4 Fluid thermal pressurization to abrupt depressurization, and friction recovery to fusion melting

Friction in the beginning stage of slip easily raises the temperature along the slip plane. In this state, the interstitial fluid of the fault zone surrounded by impermeable host rock is thermally pressurized and attains lithostatic fluid pressure (Sibson, 1973; Lachenbruch, 1980; Mase and Smith, 1987; Melosh, 1996; Rice, 2005). Only a few mm to cm slip is enough to supply the energy for the thermal pressurization (Sibson, 1973; Lachenbruch, 1980; Mase and Smith, 1987; Rice, 2005). If the lithostatic pressure is maintained, there is no effective shear strength on the slip plane which is lubricated. However, if the thermally raising fluid pressure exceeds the effective tensile strength, the pressure triggers the hydro-fracturing and implosion (e.g. Sibson, 1973; 1975). Such abrupt extensional fracturing suddenly drops the fluid pressure. The rapid decrease of the fluid pressure means that effective shear strength is recovered and shear heating goes again to fusion melting at the slip plane. Recovered friction might raise again the temperature and pressure of interstitial fluid in the damage zone and might enhance the fluid flow into the dilatant jog. Rock records observed in this study suggests such a dynamic feedback may have occurred in the stage of slip propagation of seismogenic faulting in a subduction zone, although quantitative temperature and pressure estimation due to thermal pressurization and its associated time-scale are still to be determined in the future.
