Abstract

The origin of a strong continuous radar reflector observed with airborne radio-echo sounding (RES) at the EPICA deep-drilling site in Dronning Maud Land, Antarctica, is identified as a transition in crystal fabric orientation from a vertical girdle- to increased single-pole orientation seen along the ice core. The reflector is observed with a 60 ns and 600 ns long pulse at a frequency of 150 MHz, spans one pulse length, is continuous over 5 km, and occurs at a depth of about 2020–2030 m at the drill site. Changes in conductivity as reflector origin are excluded by investigating the ice-core profile and synthetic RES data. Our observations allow to extrapolate the crystal orientation feature along the reflector in space, with implications for ice-sheet dynamics.

1 Introduction

The current demand for advanced modeling of ice sheets requires the incorporation of anisotropic properties of ice for unraveling their history and predicting their future behaviour (ISMASS Committee, 2004). The correlation between fabric changes and climate transitions (e.g. Durand et al., 2007) moreover emphasizes that valuable information is carried by vertical and lateral fabric distributions. Radio-echo sounding (RES) provides a tool to map strong fabric changes occurring over few 10s of meters in the vertical from the surface, as will be shown here.

Since the beginning of operational applications of RES in glaciological research three processes were suggested to cause continuous internal reflections from within the ice column (Bogorodsky et al., 1985; Dowdeswell and Evans, 2004): changes in density (Robin et al., 1969), conductivity (Paren and Robin, 1975), and changes in the crystal orientation fabric (COF) (Harrison, 1973). Whereas the isochronous property of reflection horizons originating from changes in density and conductivity is nowadays routinely exploited for a multitude of purposes, the detection and interpretation of reflections stemming from changes in the crystal orientation fabrics (COF) is still in

the early stages. Partial reflection of a propagating radar pulse occurs where either the real (ϵ') or imaginary part (ϵ'') of the complex dielectric constant (ϵ) changes. The possibility to detect fabric changes with RES arises from the anisotropy of permittivity in a pure ice crystal. The latest compilation of dielectric properties of ice (Fujita et al., 2000) provides an anisotropy in ϵ' of $\Delta\epsilon' = \epsilon'_{\parallel} - i\epsilon'_{\perp} \approx 0.035$, measured parallel and perpendicular to the crystal c-axis, at 1 MHz and 252 K. This value corresponds to little more than roughly 1% of the permittivity of ice, which is in the range of 3.1–3.2.

To discriminate reflections originating from changes in COF and conductivity, multi-frequency experiments can be utilized (Fujita et al., 1999). However, as ice is also a birefringent medium at radio frequencies (Hargreaves, 1978), multi-polarization measurements are required to resolve ambiguities arising from anisotropic reflection and wave propagation in a birefringent medium (Doake et al., 2002; Fujita et al., 2003). With such experiments, Matsuoka et al. (2003, 2004) located high-scattering zones several hundred meters thick at depths around 1000–1500 m in East Antarctica. Based on the dependence of reflection strength on polarization plane, the wide zone was interpreted as alternations in COF of adjacent ice layers. Fujita et al. (2006) determined the vertical evolution of the radar phase by combining ice-core profiles of COF at the same sites with a matrix-model of radar-wave propagation. By comparison with multi-polarization/bi-frequency RES point data, they determined the general contribution of anisotropic reflection from COF and birefringence to the observed signals. Unfortunately, previous studies did not provide COF data from ice cores for direct comparison with RES data.

In this work we extend previous findings by comparing RES data with ice-core profiles of COF, permittivity, and conductivity. We moreover use synthetic RES data to analyse the origin of RES signals. This leads to the novel observation that a sharp internal reflection horizon, continuous over several kilometers, is caused by an abrupt transition in crystal orientation fabric occurring over just few tens of meters.

2 Data and methods

2.1 Radio-echo sounding (RES)

The RES flight line used here runs along an ice divide (ESE–WNW direction), passing the EPICA drill site (0.0684° E, 75.0025° S, 2891.7 m) about 100 m to the NNE (Fig. 1). The RES profiles 022150 (600 ns pulse) and 023150 (60 ns pulse) shown in Fig. 2 were recorded with the system on board the Dornier 228-101 aircraft *Polar2* operated by the Alfred Wegener Institute (AWI) in season 2002/2003 at an altitude of 450 m above ground. The system, with an overall performance figure of 190 dB, generates a 150 MHz burst of 60 ns and 600 ns duration, which are transmitted alternately, resulting in a trace spacing of 6.5 m between equal pulses at typical speeds of 65 m s⁻¹ (130 knots) (Nixdorf et al., 1999). The receiver module rectifies and logarithmically compresses the signal, stacks 200 consecutive signals after analog-to-digital conversion, and stores the data on tape at sample intervals of 13.33 ns over a time window of 50 μs. For the later analysis, we consider a stack of 10 traces closest to the drill site of each pulse, referred to as the long and short RES traces, respectively (Fig. 3). Apart from static correction for the first break of the surface reflection, no additional filtering or gain control is applied to the RES traces. Conversion from recorded traveltime to depth domain is performed with the calibration for pure-ice permittivity derived by Eisen et al. (2006), with a mean wave speed of 168.7 m μs⁻¹ at 2100 m depth.

2.2 Ice-core permittivity and conductivity profiles

Dielectric profiling (DEP) at 250 kHz and γ -attenuation profiling, simultaneously carried out in the field after core retrieval, provide dielectric properties and density along the EPICA-DML ice core (see Eisen et al., 2006 for details). The calibrated DEP record was corrected for variations in core diameter and temperature. Unreliable data in the vicinity of core breaks are removed. Effects of density and conductivity mixed permittivity

(DECOMP) in the two-phase system ice–air are taken into account by applying a volumetric mixing model extended to complex space, thus separating contributions from density and conductivity in permittivity (Wilhelms, 2005).

2.3 Finite-difference forward modeling

5 The synthetic trace, adapted from Eisen et al. (2006), simulates the 60 ns pulse (Fig. 3). It is calculated by a one-dimensional finite-difference time-domain model of Maxwell's curl equations. Ice-core profiles of permittivity and conductivity, corrected for DECOMP and transformed to 150 MHz, serve as model input. Conductivity is provided in 0.02 m resolution. Because of the strong influence of the DEP-measurement
10 noise in permittivity on synthetic reflections, permittivity is smoothed over 20 m (Eisen et al., 2006). The synthetic trace thus only contains reflections which originate from changes in conductivity. Processing comprises a synchronization of the synthetic source signal to the RES direct coupling signal by a time shift of +0.1 μ s, application of a Hilbert magnitude transformation to obtain signal envelope (i.e. mimic rectification),
15 and smoothing with a 100 ns Gaussian running-mean filter.

2.4 Determination of crystal-orientation fabric

Fabric data of the EPICA DML deep ice core were measured down to 2560 m depth in a coldroom at a temperature of -20°C in 2005 at AWI (Bremerhaven, Germany). Samples were drilled between 2001 and 2004 and have been stored at -30°C
20 after the transportation at -25°C to AWI. Thin sections were prepared according to standard procedures using a microtome from horizontally ($0.5 \times 50 \times 50 \text{ mm}^3$) and vertically ($0.5 \times 50 \times 100 \text{ mm}^3$) cut samples. Orientations of c-axes were derived using an automatic fabric analyzer system (Wilson et al., 2003), which enables complete measurement of these samples in 15 to 30 min. In addition to the Schmidt diagrams
25 (mapping each measured crystal c-axis direction from a point on the hemisphere to a circular plane using an equal-area projection, Fig. 4), we present the data in terms

of the eigenvalues λ_i of the orientation tensor (Wallbrecher, 1979). The eigenvalues (Fig. 3) represent the components along the orthogonal coordinate system \hat{e}_i of an ellipsoid, which best approaches the momentum of inertia of the c-axes distribution.

3 Results and discussion

5 Drilling finished in January 2006 with reaching bedrock at a logged ice thickness of 2774.15 m. The radar profiles at both pulses show the known internal layering, which increasingly follows the bedrock topography at larger depth. The echo-free zone is present in the lowest 500–800 m depth above bedrock. The 600 ns pulse spans some 50 m in ice and integrates over a much wider depth range than the short pulse, which
10 covers only about 5 m. As could be expected, less layers are therefore visible in the profile recorded with the 600 ns pulse than in the one recorded with the 60 ns pulse (Fig. 2). Looking at single traces, it is evident that several distinct peaks in the short-pulse trace have nevertheless counterparts in the long-pulse trace. This is clearly the case for strong reflections at depths of 1810 and 2035 m, and less so at 1865 and
15 2080 m (Fig. 3). Dominant reflections of each pulse cover about one pulse length. The first break of the concurrent reflections appear at about the same depth, but the maximum power in the long pulse occurs about 10 m deeper.

The comparison between the short pulse trace and the synthetic trace carried out by Eisen et al. (2006) demonstrates that a number of internal layers can be reproduced
20 by forward modeling based on a conductivity profile. Removing dominant peaks by interpolation in the underlying conductivity profile causes a disappearance of the related reflections in the synthetic trace, as indicated for two cases at 1865 and 2080 m depth in Fig. 3 by the dotted line and the black peaks of the synthetic radargram. This demonstrates that these reflections originate from narrow peaks in conductivity
25 about 0.5 m wide. Interestingly, the strong signal in the short pulse at 2035 m is not reproduced in the synthetic data. In comparison to the reflection at 1865 m of the short pulse, which is caused by a peak with a maximum conductivity of $38 \mu\text{S m}^{-1}$ on

a background conductivity of $15 \mu\text{S m}^{-1}$, one would expect a conductivity peak of comparable size also at 2035 m. However, the conductivity profile merely displays a peak of $24 \mu\text{S m}^{-1}$ on a background of $17 \mu\text{S m}^{-1}$ at this depth. Peaks of this size appear regularly in the conductivity profile, without causing strong reflections, neither in the short pulse nor in the synthetic trace. Missing data, rejected in the DEP quality check, could mask a prominent conductivity peak. Nearest sections of data gaps longer than 0.5 m (a typical width of strong conductivity peaks) are located at 2026.26–2027.32, 2028.29–2028.81, 2038.90–2039.93, and 2040.03–2040.65 m. Each of these gaps is further away from the reflector's depth of origin than its depth accuracy of less than 1 m (Eisen et al., 2006). We therefore exclude that a single peak in conductivity causes the reflection in the short pulse trace at 2035 m.

Another possibility would be that interference of partial reflections at several peaks within one pulse length occurs. However, referring to the reflection's counterpart in the long-pulse data, it would be surprising that a series of small conductivity peaks of just $5\text{--}10 \mu\text{S m}^{-1}$ above a background of $15\text{--}20 \mu\text{S m}^{-1}$ would allow for coherent interference in both pulse lengths to produce the narrow and dominant reflections. We therefore also exclude the possibility that the reflections at 2035 m in both RES traces are caused by changes in conductivity, and thus the imaginary part ε'' of the dielectric constant.

The only other possibility for reflector origin is the real part ε' . At these depths, changes in density are not present, as air bubbles already turned into air hydrates. Consequently, one would expect a constant permittivity profile, and also a constant permittivity. The noise seen in the profile of about 0.05 on the sub-meter scale (Fig. 3) is attributed to measurement noise of the DEP bench. We therefore cannot use the permittivity profile to determine the reflection origin. The remaining possibility to cause a change in ε' are changes in COF. The Schmidt diagrams show a transition from a vertical girdle-type to a single-maximum fabric with c-axes clearly concentrated around the vertical at 2025–2045 m depth (Fig. 4). The eigenvalues of the distribution of c-axes (Fig. 3) show this transition very clearly in the two largest components λ_2 and λ_3 of the vertical sections, which change by $\sim 20\%$ over 20 m. The change in eigenvalues of

the horizontal sections is only slightly smaller. However, as horizontal sections were measured almost 50 m apart, we cannot determine from these over which depth range the narrow transition actually occurs.

The distribution of c-axes allows us to calculate the permittivity components. Following Fujita et al. (2006), the effective permittivity in the direction of the ellipsoid's principle components \hat{e}_i can be determined from the eigenvalue λ_i by $\varepsilon'_i = \varepsilon'_\perp + \Delta\varepsilon' \lambda_i$. In the present case, the principle component \hat{e}_3 is very close to the vertical below 1700 m depth (Fig. 4), and $\hat{e}_{1,2}$ lie in the horizontal xy -plane. The principle components \hat{e}_i are therefore approximately aligned with the orthogonal coordinates x, y, z .

The change in COF between 2025 and 2045 m observed in the vertical sections results in a change in the permittivity components, $\delta(\varepsilon'_x, \varepsilon'_y, \varepsilon'_z) = \Delta\varepsilon' (0.6, 21.1, -20.5) 10^{-2} = (0.2, 7.4, -7.2) 10^{-3}$. This change occurs over 20 m, well within the width of the long pulse. The radar wave propagates in the vertical direction, so only $\delta\varepsilon'_{x,y}$ can cause a reflection. Following Paren (1981) and approximating $\delta\varepsilon'_y \gg \delta\varepsilon'_x$, this corresponds to a reflection coefficient of -64.5 dB. Considering the change from 2035 to 2045 m, a distance relevant for the short pulse, the reflection coefficient amounts to -68.8 dB.

The nearby reflections at 2080 m, appearing for both pulse lengths, provide a plausibility check for the hypothesis that the change in COF is indeed strong enough to cause reflections. As shown by the synthetic trace, the reflection origin is the conductivity peak at 2080 m with a height of $37 \mu\text{S m}^{-1}$. The reflection coefficient corresponding to this peak results as -75.7 dB at 150 MHz, about 7–12 dB smaller than the reflection coefficient resulting from the change in COF. The smaller reflection coefficient is consistent with the fact that the reflections' maximum peak power at 2080 m are smaller than those at 2035 m. We can therefore indeed attribute the origin of the observed reflections at 2035 m to the change in COF, which is strong enough and occurs over a short enough distance to cause the strong reflections in the short and long pulse data.

Laterally, the COF-reflector is quasi parallel to other internal layers, e.g. the

conductivity reflectors at a depth of 1865 and 2080 m at the drilling site, but displays stronger variations in reflection magnitude (Fig. 2). In the 600 ns pulse data, the conductivity reflector at 1865 m is dominant, also the radargram contains more noise than the 60 ns data. Both conductivity reflectors can clearly be tracked over the whole section of the 60 ns pulse in Fig. 2. The COF-reflector seems to be continuous in the 600 ns data as well, also only of very low quality. In contrast, it can only be tracked between -3 km and 2.5 km in the 60 ns data. It is very strong on the downstream side of the anticline between -3 and 1.5 km. Further upstream from the anticline, it fades away, with several strong reflectors appearing within 20 m above it. Downstream from the drill site, it starts to fade away at 1.5 km, and is interrupted and lost in the syncline starting around 3 km. The different characteristics of the 60 ns and 600 ns pulse emphasize that care has to be taken when interpreting long-pulse radar data, as reflector characteristics and mechanisms could change within the pulse length without resulting in obvious changes in the reflectivity or depth. The variation of reflection magnitude of the COF-reflector suggests that fabric changes are less continuous than conductivity characteristics, as they are susceptible to variations of internal stresses, e.g. between upstream and downstream sides of subglacial bedrock variations.

4 Conclusions

The combination of ice-core profiles of COF and conductivity with RES data of different pulse lengths in our approach identifies the origin of a defined continuous internal reflector as a sharp transition in COF, from a girdle-type to a single-maximum fabric over just few tens of meters. This finding goes beyond previous analysis, which related RES signals to COF, but did not provide a direct comparison of nearby in-situ data of COF. We showed that, even at short pulse lengths, the width of the COF-related reflector is comparable to reflectors stemming from conductivity peaks, limited by the RES pulse length. The spatial variation of the COF-reflector in depth is parallel to other isochronous reflectors. Both observations imply that care has to

be taken when correlating ice-core data with internal reflectors if only single-frequency single-polarization RES data are available.

The identification of a single change in COF as the origin of a strong individual internal reflector opens new possibilities for understanding ice dynamics. The fabric properties can be extrapolated along the reflector, as long as it is continuously trackable in the RES profile. Determination of the internal distribution of stresses can thus go beyond the point information provided by ice cores. Ice-dynamic models can likewise utilize the reflector as an ancillary condition. As the rheology of a girdle-type fabric differs from those of a single-maximum fabric, the reflector indicates a boundary of different rheological regimes above and below the reflector within the ice sheet. A remaining challenge lies in exclusively using remote-sensing data, like RES or seismics, to discriminate physical properties from the ice sheet's surface, without requiring in-situ information from ice cores. By providing characteristic observations of the forward relation of changes in COF and reflectivity, this study provides another step towards solving the inverse problem, which should eventually be used to determine continuous profiles of vertical and lateral physical properties.

Internal RES reflector
originating from COF

O. Eisen et al.

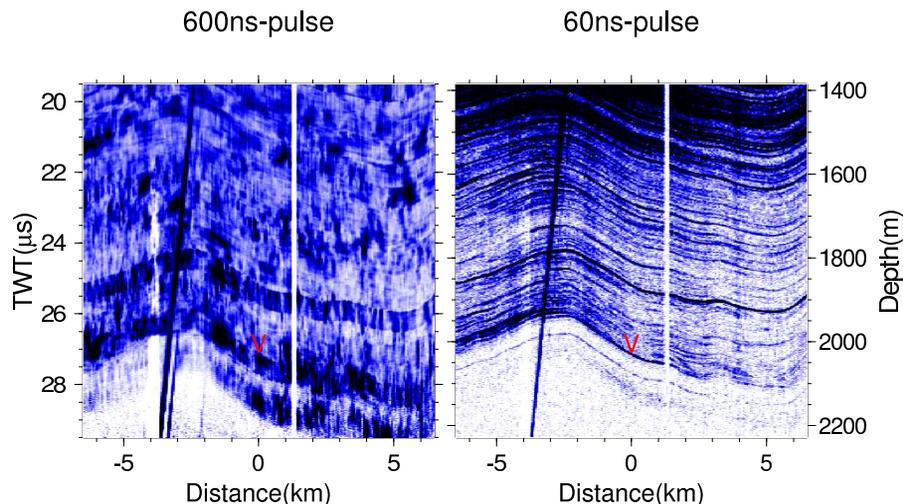

Fig. 2. Unfiltered 10-fold stack RES profile recorded with the 600 ns pulse (022150, left) and 60 ns pulse (023150, right). Ordinates are the same for both panels: two-way traveltime (TWT) on left ordinate is uncorrected recording time, right ordinate refers to depth below surface; color code indicates signal magnitude (increasing white-blue-black); red arrows indicate first break of internal reflector of interest for both pulses at the drill site; reflections from Kohnen station (at profile center) cause the hyperbola leg between -3.8 and -2.3 km; white vertical line at 1.3 km is caused by system dropout. Ice flow is from left to right (ESE–WNW), the profile runs approximately parallel to a transient ice divide.

Internal RES reflector
originating from COF

O. Eisen et al.

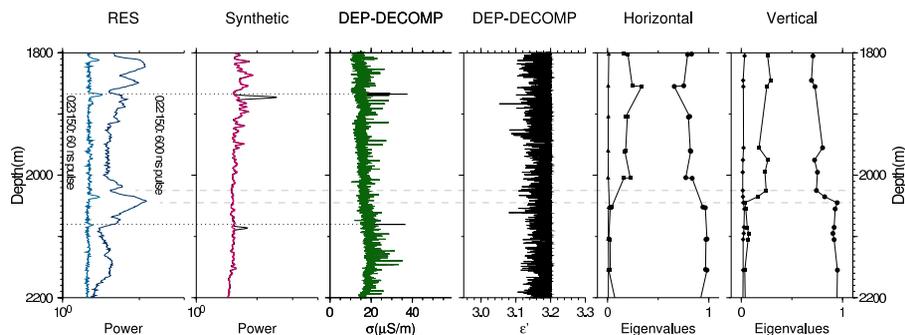

Fig. 3. Comparison of radar data and ice-core profiles at the EPICA-DML drilling site. From left to right: measured RES trace for two pulse widths from profiles 022150 (600 ns pulse) and 023150 (60 ns pulse); DEP-based synthetic RES trace for 60 ns pulse; DECOMP-corrected DEP conductivity (σ); DECOMP-corrected DEP-permittivity (ϵ' , with the permittivity of pure ice as upper bound); eigenvalues of crystal orientation tensor along horizontal and vertical sections. The black synthetic trace is based on original conductivity data (black σ -curve); on top the red synthetic trace is plotted, based on the DEP data with removed conductivity peaks (green σ -curve); peaks originating from conductivity thus appear black, emphasized by dotted horizontal lines; dashed horizontal lines connect depth of strong RES reflector with transition depth of changes in COF.

Interactive Discussion

**Internal RES reflector
originating from COF**

O. Eisen et al.

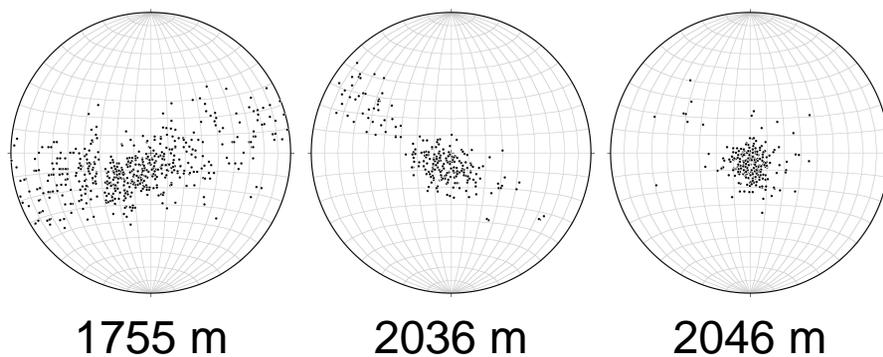

Fig. 4. Schmidt diagrams of vertical sections at three depths, showing the orientation of c-axes and the transition from girdle-type to increased single-maximum fabric. The orientations have been rotated into the horizontal xy -plane. The majority of c-axes at 2046 m are oriented in the vertical.
