## Abstract

The Çatallar Basin is one of the Miocene basins located in the southern part of the Bey Dağları Massif (SW Turkey). This basin has been reinvestigated and new stratigraphic and sedimentological data are now presented. The Çatallar Basin lies in paraconformity on the Bey Dağları carbonate platform of Late Cretaceous to Palaeogene age. It consists of an impersistent, shallow-marine carbonate base (Karabayır formation, Late Oligocene to Early Burdigalian) followed by an onlapping detrital sequence including the Akçay and Bağbeleni formations (Langhian to Serravallian). The Akçay formation mainly contains turbidites in which several debris-flows and olistostromes are intercalated. The lowest debris flows derive from the local carbonate platforms of Cretaceous and Palaeogene age. Higher, the debris flows and olistostromes contain large carbonate blocks deriving from nearby sources (Bey Dağları platform carbonates), whereas the accompanying pebbles originate from the allochthonous ophiolitic units located farther to the north (Lycian Nappes) or to the east (Antalya Nappes). The origin of these ophiolitic detritus is a matter of debate. The new data obtained in this study favour a northern origin.

**Keywords:** Sedimentology; Biostratigraphy; Source of detritals; Miocene; Basin analyses; Lycian Nappes

## 1. Introduction

In southwestern Turkey, two sets of nappes are thrust over the Bey Dağları carbonate platform: the Lycian Nappes to the northwest, and the Antalya Nappes to the east ([Brunn et al., 1971], [Poisson, 1977], [Gutnic et al., 1979] and [Robertson, 2000]).

The Antalya Nappes were first emplaced during the latest Cretaceous and the Paleocene upon the southeastern margin of the Bey Dağları platform ([Poisson, 1977], [Gutnic et al., 1979]

and [Robertson, 2000]). Although strongly debated, their origin from the southern branch of the Neotethys is generally accepted now (see discussion in [Robertson et al., 2003] and [Poisson et al., 2003b]).

The Lycian Nappes, issued from the Northern branch of the Neotethys were initially thrust southwards upon the margin of the Anatolian micro-continent during the Late Cretaceous. Subsequent southwards thrusting across the Anatolian micro-continent brought the Lycian Nappes to their present position during the Langhian (Poisson, 1977). The tectonic emplacement and the following erosion of the Lycian units were responsible for the development of a Miocene foreland basin along the thrust front (Lycian Basin, Fig. 1) (Flecker et al., 2005), but also for the deposition of finer detritals that were spread over most of the Bey Dağları platform during the same period. The final infill of these basins during the Middle to Upper Miocene provides reliable insights about the nature of the eroded rock units, and reflects the chronology of the coeval tectonic events in the region.

Presently, only the edge of the Lycian Basin is exposed along the SE front of the Lycian Nappes. Most of the basin is hidden below the nappes except for a tectonic window near Göcek, 75 km from the thrust front (insert in Fig. 1). The succession of the detrital formations infilling the Lycian Basin during Burdigalian and Langhian reflects the progression of the Lycian Nappes towards the Bey Dağları platform. The first deposits (Middle Burdigalian) are distal turbidites in a deep environment indicating that the front of the nappes was still far away to the north. By the end of the Burdigalian and early in the Langhian, coarser clastics (sandstones and micro-conglomerates) are deposited in a shallow-marine environment. Last, fluvio-marine and deltaic coarse conglomerates with occasional coral reefs (Middle Langhian) complete the detrital sequence of the Lycian Basin, just before the final emplacement of the nappes. A regional emersion of the Lycian units and of large parts of the Bey Dağları during the Late Langhian is indicated by the arrival of polymictic clastics into the outer Miocene basins located further south. Among these, lies the Kasaba Basin ([Poisson, 1977] and [Hayward, 1982]) where shallow-marine alluvial fan and fan deltas along its NW margin show that its filling immediately followed that of the Lycian Basin.

Farther away southwards, the Çatallar, Sidek and Salur Basins are smaller, partly coeval Miocene basins, situated on the Bey Dağları platform. During the Middle and Late (?) Miocene, these basins were filled with fine to coarse detritals coming from allochthonous units containing ophiolites. Owing to the position of these basins (Fig. 1 and Fig. 5) their source rocks could either be situated in the Lycian Nappes to the northwest or in the Antalya Nappes to the east. Although the Lycian origin of the ophiolitic detritals filling the Kasaba Basin is not disputed ([Poisson, 1977] and [Hayward, 1982]), the origin of the ophiolitic conglomerates present in the Çatallar and in the Salur Basins is more controversial.

On the basis of facies and biostratigraphic studies in the Çatallar Basin, Poisson and Akay (1981) suggested that the ophiolitic materials also derived from the Lycian Nappes during the Langhian, as in the neighbouring Kasaba Basin. On the opposite, Hayward and Robertson (1982), on the basis of current direction measurements, concluded that the ophiolitic pebbles both in the Çatallar Basin and in the Salur Basin derived from the Antalya units during the Early Miocene, and considered it as an evidence for a southern origin for the Antalya units.

Presently, two critical issues are thus disputed in the Çatallar and Salur Basins: the timing (Early Miocene or Middle Miocene) and the origin of the source of the ophiolitic detrital material: from the north or northwest (i.e. from the Lycian Nappes), or from the east (i.e. from

the Antalya Nappes). We have reinvestigated the Çatallar Basin in order to check both models with a 1/25,000 scale mapping, a reappraisal of the facies analysis and a precise stratigraphy based on planktic foraminifera.

## 2. The Çatallar Basin

### 2.1. Geological setting (Fig. 1, Fig. 2, Fig. 3, Fig. 4 and Fig. 5)

The Çatallar Basin is located 20 km north of Finike and was connected with the Salur and Kasaba Basins during the Miocene (Fig. 1). The Çatallar Basin was deformed by Late Miocene to Pliocene tectonic events which affected SW Turkey (Aksu Phase, [Poisson, 1977], [Frizon et al., 1995] and [Poisson et al., 2003a]). As a result, the Çatallar Basin was isolated from the adjacent basins, and the Bey Dağları and Susuzdağı platform units overthrust parts of its northern and eastern margins which are now hidden (Susuzdağı Thrust, [Uysal et al., 1980] and [Şenel, 1997]) (Fig. 2).

### 2.2. Lithostratigraphic type succession

Following the first stratigraphic studies of the basin ([Poisson, 1977] and [Uysal et al., 1980]), Hayward (1982) provided a detailed description of the facies and the formations, and recognised the sedimentary interfingering of several lithological units. A complete sequence of the basin fill can be seen between Gökbük and Başkoz (Fig. 2), and a synthetic litho- and bio-stratigraphic log of the basin is presented in Fig. 3. We propose here a new interpretation of the Çatallar Basin, which includes a revision of Hayward's nomenclature, as follows:

#### 2.2.1. Karabayır formation

This formation was first described on the western side of the Bey Dağları anticline (Poisson and Poignant, 1974) and consists of shallow-marine calcarenous limestone grading upward into deeper micritic facies. The calcarenites include red algae, benthic foraminifera, echinoderms, molluscs and corals of Late Oligocene to Aquitanian age (Fig. 6A). Above, the micritic limestones contain a rich assemblage of planktic foraminifera of Early Burdigalian age. In the Çatallar Basin, this formation is present only locally but is frequently found as pebbles in the overlying conglomerates and as olistolites in the olistostromes, suggesting that the former extension of the Karabayır formation was much wider in the region (Mk in Fig. 9).

#### 2.2.2. Akçay formation

The Akçay formation records the first detrital input into the basin. This formation was described near the village of Yalnız (former name: Akçay) by (Hayward, 1982) and (Hayward and Robertson, 1982). The base consists of turbidites (Langhian), followed by debris flows and olistostromes containing ophiolitic debris. Five facies (F1: green mudstone-calcareous sandstone–carbonate alternations; F2: parallel stratified calcareous sandstone–siltstone alternations; F3: matrix-supported conglomerate; F4: olistostromes; F5: limestone breccia) have been identified within the Akçay formation and are described in detail in Table 1 and illustrated in Fig. 6, Fig. 7 and Fig. 8. The depositional environment of the Akçay formation indicates deep marine conditions, as suggested by turbiditic sandstones (F1 and F2, Fig. 6B–F) and olistostromes (F4, Fig. 7C–D). The large predominance of planktic foraminifera indicates a basin several hundred meters deep. In the shallower parts of the basin, matrix-

supported conglomerates (F3) representing fan deltas (Fig. 7A–B) and breccias from colluvial cones (F5, Fig. 7E–F) are also present.

### **2.2.3. Bağbeleni formation**

This conglomeratic formation was described by Hayward (1982) as a member of his Kemer formation. The type section is situated between the villages of Çatallar and Bağbeleni (Fig. 2). Two facies (F6: clast- to matrix-supported imbricated conglomerate and F7: clast-supported conglomerate) are described within the Bağbeleni formation (Table 1), and illustrated in Fig. 7 and Fig. 8.

Contrasting with the deep marine environment of the Akçay formation, the environments of the Bağbeleni formation are generally shallower, and end with shallow-marine to sub-aerial deposits. The age of deposition is younger, most probably Late Langhian to Serravallian, reaching the Tortonian at the top (Fig. 3). The Bağbeleni formation is dated indirectly through reworked pebbles, and by the dating of mudstones and sandstones considered as a lateral facies equivalent in the southeastern part of the basin (see sections Sections 1 and 2 in Fig. 4a). To the north (Başkoz and Günçalı Yayla), the age of the Bağbeleni formation derives from mudstone intercalations containing planktic microfaunas (sections 3–5 in Fig. 4a).

## **2.3. Lateral variations**

Both formations described above were initially mapped within the Çatallar Basin but have been followed farther to the north, although they may not be present altogether in each section. North of Çatallar village, the Susuzdağ Thrust hides a substantial part of the basin, nevertheless, in the northwestern area, similar successions are present (Fig. 4b, sections 6–8), with alternating mudstones and sandstones (Akçay formation), followed by an olistostrome in the Arif area and, further to the north, by thick conglomerates (Bağbeleni formation) which include pebbles of gabbros, serpentinites, peridotites (up to 30–40 cm in size), radiolarites, metamorphic rocks and various carbonates (F6 and F7, Fig. 8). A similar succession is present near Başkoz village and in the Hördübék and Günçalı Yaylas (Fig. 2), and extends further west in the Kasaba Basin where it joins other coarse detritals issued from two fan deltas near Ortabağ and Doğantaş villages (Fig. 1). The latter also contain ophiolitic pebbles derived from the Lycian Nappes ([Önalan, 1979], [Hayward, 1982] and [Hayward and Robertson, 1982]).

## **2.4. Biostratigraphy**

The stratigraphy in the Çatallar Basin is mainly based on planktic foraminifera assemblages (Table 2), and accessorially on benthic microfauna in the neritic limestones of Aquitanian age. In their new biostratigraphic and chronostratigraphic scale, Iaccarino and Premoli Silva, 2005 define the Langhian stage differently from that of Iaccarino (1985): Langhian is calibrated from 15.9 to 13.6 Ma. It begins with the *sicanus* FO (first occurrence) and ends just before the *periferoronda* LO (last occurrence). In this scale, *Orbulinas* appear in the middle part of the stage. In Iaccarino (1985), Langhian also begins with the *sicanus* FO, but is shorter, and ends with the appearance of *Orbulinas*, precisely between *O. suturalis* and *O. universa* FO's. In order to ensure an easier correlation with other Miocene basins in Turkey and in the eastern Mediterranean region, we follow the stratigraphic concept of Iaccarino (1985) in this paper. The chronostratigraphy is based on the biozones (N5 to N14 in Table 2) defined by planktic

assemblages, but the stages boundaries (Burdigalian, Langhian, Serravallian), are only indicative as their limits are still under discussion.

Previous studies ([Poisson, 1977], [Uysal et al., 1980] and [Poisson and Akay, 1981] used by Hayward (1982) provided the first stratigraphical data for the base of the basin in the Çatallar–Gökbük area and showed that an important gap (Early Miocene) existed between Oligocene and Langhian deposits. However, this gap seems only local as limestones of latest Oligocene to Aquitanian age are present within the Karabayır formation. However, in many places, the Lower Miocene deposits were eroded during the Burdigalian–Langhian transgression (Poisson and Akay, 1981) and only fragments are present as reworked pebbles in the Langhian conglomerates.

Burdigalian deposits (muddy limestones) were also largely eroded and reworked during Langhian. The precise transition from Aquitanian to Burdigalian (Fig. 4a section 3, sample 83: N5 zone) is present within a reworked block of planktic limestone in the lowermost olistostrome of the Akçay formation, near Çatallar village. Thus, most of the Akçay formation and the lower part of the Bağbeleni formation are Langhian in age, and exhibit a high rate of detrital sedimentation (Table 1 and Fig. 3). The end of the basin infill occurred during Serravallian, as shown in the upper half of the Bağbeleni formation and its lateral equivalents. Only one sample, situated in the upper part of the Bağbeleni formation (Fig. 4a section 1, sample 52: N14 zone) and containing *Globigerina nepenthes* associated with *Neogloboquadrina paeatlantica* could be attributed to Early Tortonian. Unfortunately, the uppermost deposits of the Çatallar Basin are hidden under the Susuzdağ Thrust.

### **3. Origin of the olistolites and of the ophiolitic detritals in the Çatallar Basin: discussion**

As concerns the origin of the detritals in the Çatallar Basin and in the adjacent Kasaba and Salur Basins, various arguments have been considered. Among them, the lithology of reworked materials, sedimentological data and possible source rocks have been spotted in the nearby platform carbonates and in the allochthonous units situated farther away ([Poisson and Akay, 1981] and [Hayward, 1982]).

#### **3.1. Origin of the large carbonate olistolites and of the debris flows**

Owing to their size (F4, Fig. 7C–D), the large carbonate olistolites most probably derive from the nearby carbonate platforms in the Alacadağ and in the Pancarlı Dağ (Fig. 2 and Fig. 9) where similar facies of Upper Cretaceous *Globotruncana* limestones, Eocene nummulitic limestones and planktic Burdigalian micrites are present.

West of Gökbük village (Fig. 2), shortly travelled debris-flows containing only carbonate pebbles with coral fragments in a sandy matrix most probably have also a local origin such as Alacadağ to the west of the Çatallar Basin. Higher, the debris flows contain various materials such as gabbros and other ophiolitic debris of distant origin mixed with locally derived carbonates (Aquitanian algal limestones, coral fragments, Eocene and Cretaceous limestones), embedded in a sandy matrix (facies F3, Fig. 7A–B). Several occurrences are present in debris flows near Çatallar village along the new road to Finike, at the cross section of the Elmali and Kasaba roads, and in the Yazır corridor (Fig. 2).

## **3.2. Origin of the ophiolitic clasts**

### ***3.2.1. Arguments from paleogeographic data***

The origin of the ophiolitic clasts is controversial. On the basis of similar ages and type of deposition (olistostromes with coarse pebbles), Poisson and Akay (1981) have compared the Çatallar olistostrome with the Kemer fan delta in the Kasaba Basin (Fig. 2), and suggested that both should have the same origin, i.e. derived from the Lycian Nappes located to the north. On the opposite, Hayward and Robertson (1982) relying on flow directions measurements in the region favoured an eastern origin for the Çatallar debris flows, i.e. from the Antalya units. However, their conclusion is based on the combination of two distinct sets of data, one from the Çatallar Basin itself, and another set measured in the Salur Basin with a poorer stratigraphic control. Our measurements are in agreement with those concerning the Çatallar Basin (i.e. showing a northern origin), and precise ages (Langhian–Serravallian) are provided here for the related detritals. In contrast, the age of the coarse detritals in the Salur Basin, where the most significant eastern directions recorded by Hayward and Robertson (1982) come from, is not tightly constrained and is possibly younger in part, as suggested by the Late Miocene thrust of the Antalya units situated immediately above. Hence, in spite of the similar aspect of the Miocene conglomerates in the Çatallar and in the Salur basins, two distinct detrital sources are probably present, and require that both sets of data should be considered separately.

The Çatallar olistostrome and the fan deltas in the Kasaba Basin have the same age (Langhian), which is precisely the age of the latest translation of the Lycian Nappes onto the Bey Dağları, as shown by the youngest deposits in the Lycian Basin in front, which are polymictic conglomerates deriving from the arriving Lycian Nappes (Fig. 9A). These conglomerates contain abundant ophiolitic blocks and pebbles and were part of sub-emergent fan deltas, including coral reefs from place to place ([Poisson, 1977], [Gutnic et al., 1979], [Hayward et al., 1996], [Tuzcu and Karabiyikoğlu, 2001] and [Karabiyikoğlu et al., 2005]). The direction of transport of this coarse material is grossly from north to south (or NW to SE) towards the Kasaba Basin, through the Susuzdağ platform. Unfortunately, remnants of such deposits are absent in the central part of the Susuzdağ owing to the erosion which followed the Upper Miocene-Pliocene and Recent uplifts in the area. In contrast, the distal and deepest parts of the fan deltas are preserved along the northern margin of the Kasaba Basin near Kemer (western end) and in the Ortabağ and Doğantaş area (eastern end of the Kasaba Basin, Fig. 1). In these areas, the fan deltas are transitional with more distal facies (mudstones and graded sandstones) situated in the central part of the basin. The frequent intercalation of an abundant shelly fauna and plant remains with poor planktic microfauna suggests a shallow-marine environment, close to a landmass. The detrital connection can be followed from the Kasaba Basin to the Çatallar Basin, through the Yazır corridor and the Başkoz corridor, as shown by the coarse polymictic conglomerates of the Bağbeleni formation below the Susuzdağ Thrust (Fig. 1, Fig. 2 and Fig. 4). Hence, during the Langhian coarse ophiolitic debris can be traced from the front of the Lycian Nappes down to the Çatallar Basin through the Günçalı-Hördübék-Başkoz corridor (see map Fig. 1). These deposits substantiate a coeval detrital output linking the front of the Lycian Nappes to the Kasaba and the Çatallar Basins as remnants of larger fan deltas now preserved below the Susuzdağ Thrust (Fig. 9B and C).

### ***3.2.2. Arguments from sedimentological data***

In the Akçay formation, fine-grained distal turbidites (facies F1 and F2, Fig. 6B–F) together with *in situ* planktic foraminifera microfauna indicate a pro-delta to deep marine environment. The deepest part of the basin was located in S and SE. In addition, some of the current directions measured from the flute casts at the base of turbidites to the south of Yalnız village indicate paleocurrents from N or NE, in agreement with Hayward (1982) data. However, these data are not conclusive as in the deeper parts of the basin directions of currents could easily change. Besides, flute cast measurements from the turbidites in the southeastern part of the Çatallar Basin indicate that paleocurrent directions are scattered from NW to SE (Fig. 2).

In the Bağbeleni formation, pebble imbrications indicate paleocurrents coming from the North or NW in majority (Fig. 2), as in Hayward's data (1982). Moreover, the location of polymictic debris-flows along the northern and western borders of the Çatallar Basin also favours a northern origin of the detrital materials. This is also suggested by a change of facies from coarse to fine detritals and the decrease of the size of pebbles from NW to SE. Narrow distributary channels filled with coarse clasts in the proximal part of the fan delta near Başkızı village (NW) are replaced by finer sediments in the Yalnız area (SE).

As a conclusion concerning the origin of the clastic materials in the Çatallar Basin, most of the sedimentological data suggest a northern origin with the exception of the turbidites, which are not conclusive.

#### **4. Conclusions: Origin of the ophiolitic detritals and significance of the Miocene basins in SW Turkey**

The Çatallar Basin and the related outcrops of Lower-Middle Miocene age in SW Turkey appear as remnants of a former widespread sedimentary cover which spread over most if not all the southern part of the Bey Dağları Massif.

Until Early Miocene, the Çatallar area was part of the southern Bey Dağları platform as it followed the same sedimentary trends (Poisson, 1977). However, from the Burdigalian onwards, this area evolved independently, commencing with a marked subsidence similarly to the Lycian Basin but, unlike the latter, the Çatallar Basin contains Burdigalian pelagic limestones with planktic foraminifera, showing that until the transition Burdigalian–Langhian, this area remained out of reach of the ophiolitic debris and other detritals issued from the Lycian units. This suggests that some kind of trap-barrier existed in between, and was probably situated where the Susuzdağ now stands (Fig. 9A). This trap was most effective during the Early and Middle Burdigalian and prevented the northern influx of clastic materials to spread into the Kasaba and Çatallar Basins (Poisson, 1977). Early in the Langhian, however, this barrier no longer existed, indicating that the filling of the Lycian Basin was completed. Subsequently, during Langhian, Serravallian and later on, the feeding deltas migrated southwards, and detritals were shed farther, into the southern basins (Kasaba, Çatallar and Sidek Basins) (Fig. 9B).

Concerning the Çatallar Basin the presence of calcareous debris flows and olistostromes of Langhian age reflects local tectonic events which controlled part of the sedimentation. The restricted localisation of the largest calcareous olistolites (Fig. 2) along the western border of the basin, and their ages (Late Cretaceous, Middle Eocene, Early Miocene) suggest that normal faulting affected that side of the basin (Alacadağ and Pancarlı Dağ) during the Langhian. As a matter of facts, west of Akyaka a small half-graben filled with Langhian mudstones is bounded by a normal fault striking SW-NE which could have been active during

the sedimentation. Whatever the case, such tectonic events, and the related debris flows andolistostromes, seem specific to the Çatallar Basin.

The onset of a polymictic detrital sedimentation into the Çatallar Basin (Akçay formation) during the Langhian is coeval with the latest episode of emplacement of the Lycian Nappes onto the Bey Dağları platform. Higher, the conglomerates of the Bağbeleni formation reflect shallow-marine to subaerial conditions during the Serravallian and early in the Tortonian. In agreement with the clast composition and the palaeocurrent directions, this detrital material originate from the Lycian Nappes and must have travelled a long way from the North through the southern Bey Dağları, although direct evidence is lacking (Fig. 9C). In the Kasaba Basin, the Doğantaş, Kemer and Ortabağ fan deltas also contain polymictic detritals coming from the Lycian Nappes through the Susuzdağ (see map Fig. 1). Northwest of the Çatallar Basin, the Başkoz-Hördübék and Günçalı Yayla corridor contain remnants of similar detrital bodies exhibiting similar palaeocurrent directions, thus substantiating the Lycian provenance of the ophiolitic detritals (Bağbeleni formation) which filled the Çatallar Basin during the Middle Miocene.

In a wider view, the Lycian Basin, the Kasaba Basin and the Çatallar Basin record the progressive sedimentation of north-derived polymictic detrital materials on the Bey Dağları platform, and thus may be considered as parts of a larger foreland basin to the Lycian Nappes. This interpretation seems more appropriate than a previous model (Hayward and Robertson, 1982) in which the Antalya units were considered as the only source of the Çatallar detritals, after passing through the Salur Basin situated further east. A closer examination of the latter is presently in progress.

## Acknowledgements

The Akdeniz University in Antalya, the French Embassy in Ankara and ISTO in Orléans University supported the fieldwork and greatly facilitated scientific exchanges. Thin section preparations were carried out in Orléans University and in Hacettepe University in Ankara. The authors gratefully acknowledge the above institutions and thank C. Göncüoğlu, B. Varol and B. Natalin for their critical reviews and constructive comments.

## Figures

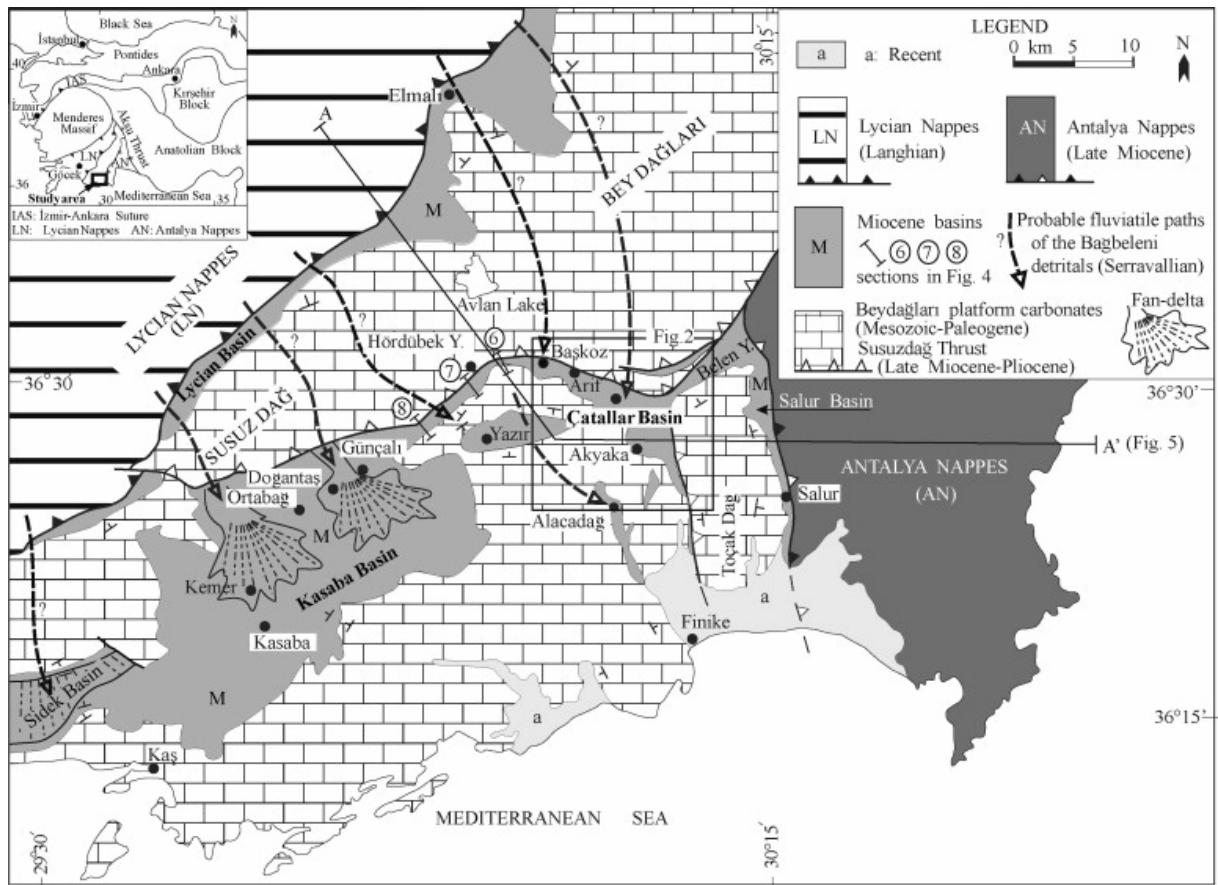

Fig. 1. Schematic map of the Neogene basins in SW Turkey and location of sections 6–8 shown in Fig. 4b. Insert: localisation of the study area. The Izmir-Ankara Suture (IAS) corresponds to the remnants of the Northern Neotethys Ocean from which the Lycian Nappes derived for a part. In this context the Menderes Massif appears as a tectonic window. The Antalya Nappes derived from the Southern Neotethys, a remnant of which is represented by the eastern Mediterranean Sea.

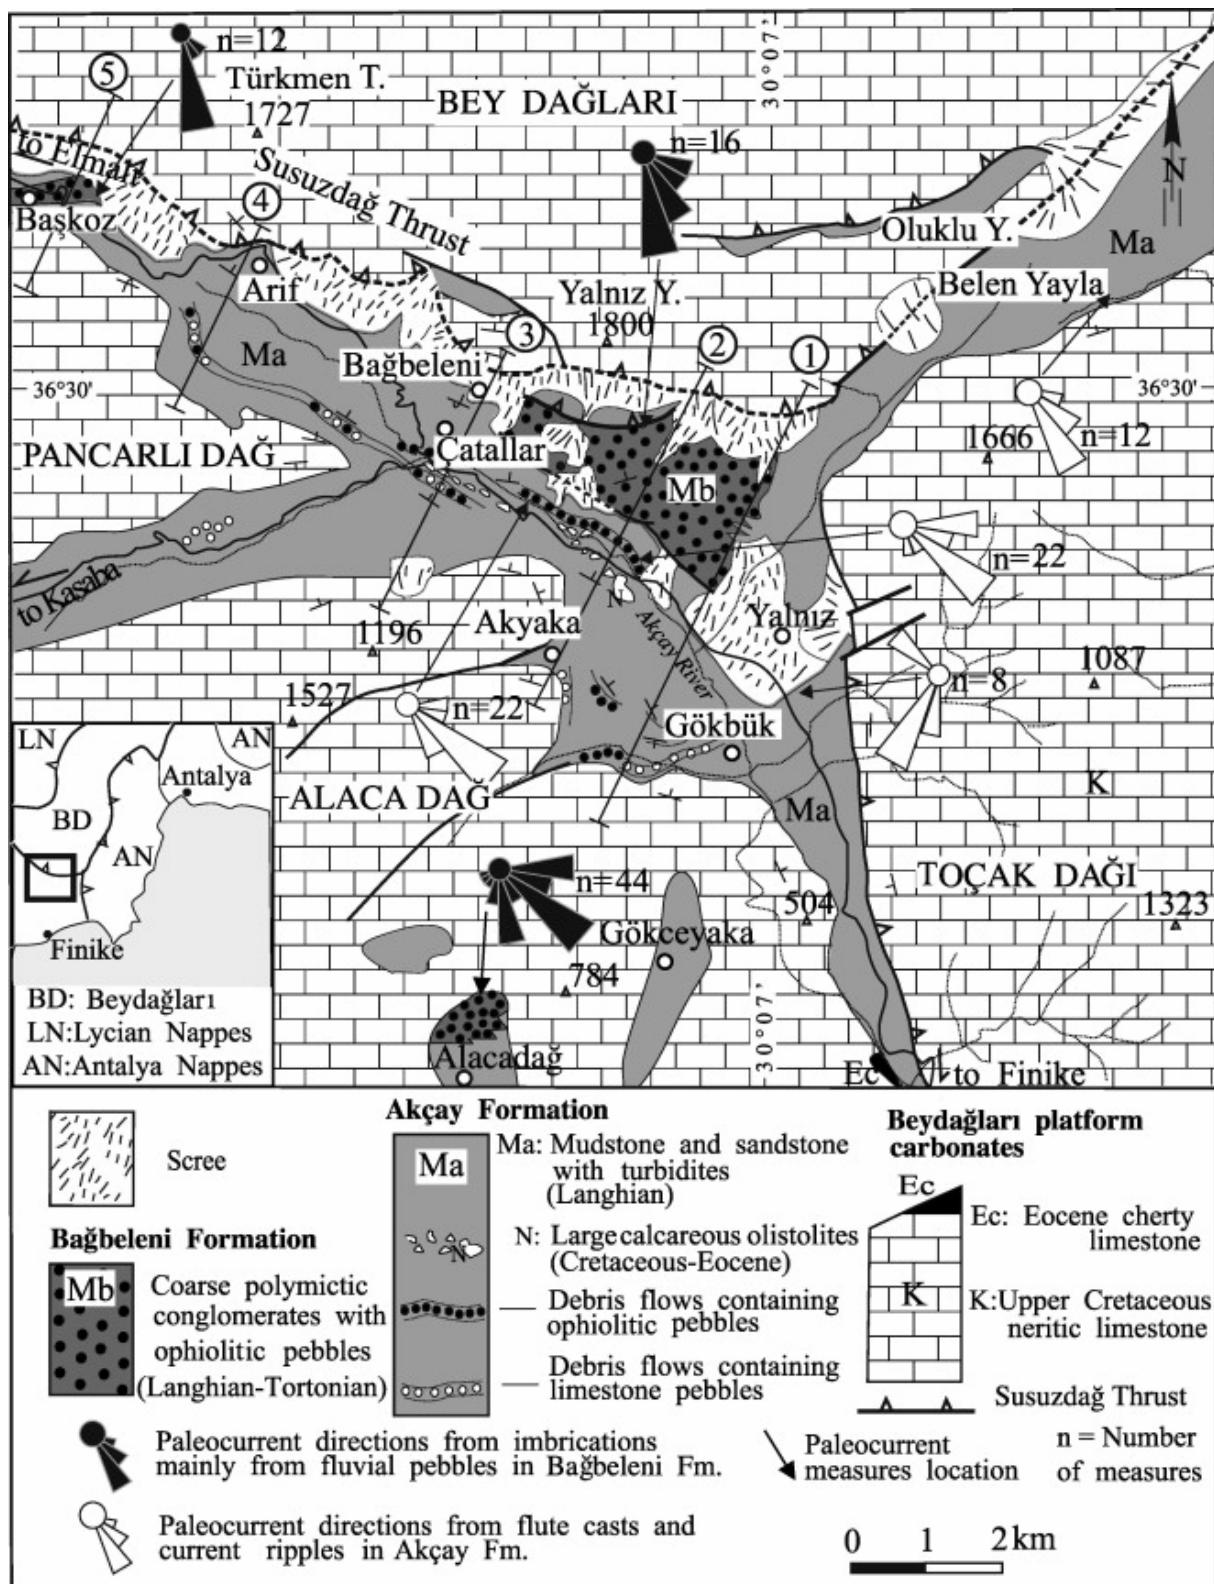

Fig. 2. Geological map of the Çatallar Basin with location of the measured palaeocurrent directions and sections 1–5 shown in Fig. 4a.

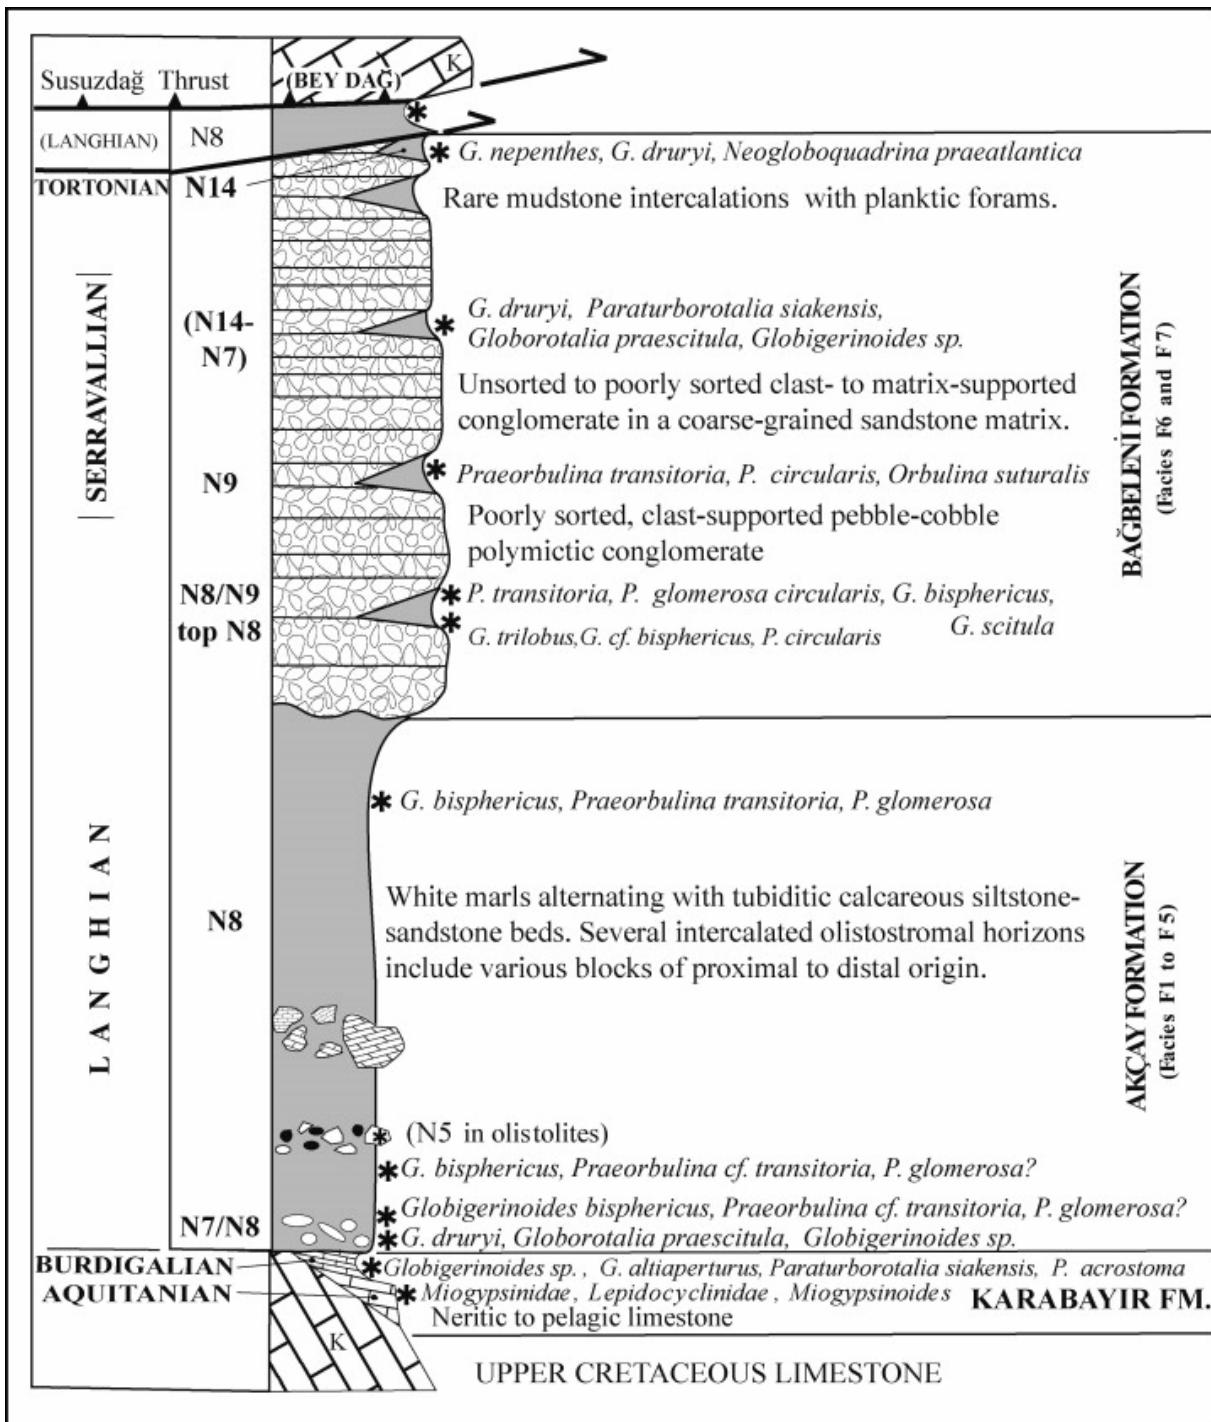

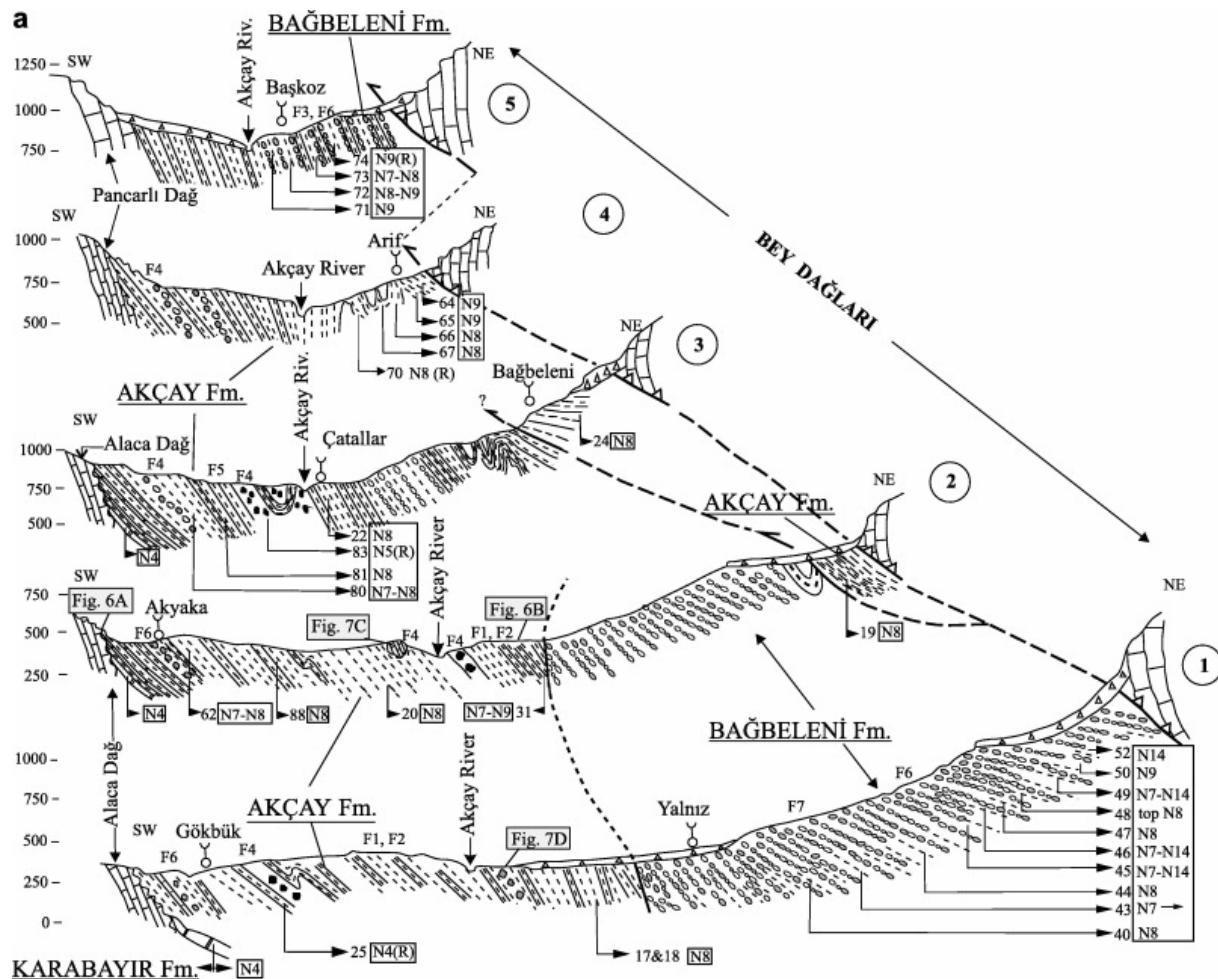

Fig. 3. Synthetic stratigraphic log of the Çatallar Basin formations showing the position of the diagnostic planktic assemblages (Biozones N5 to N14, see Table 2), and the main detrital facies (F1 to F7, see Table 1). Biozone N6 has not been characterised by planktic foraminifera.

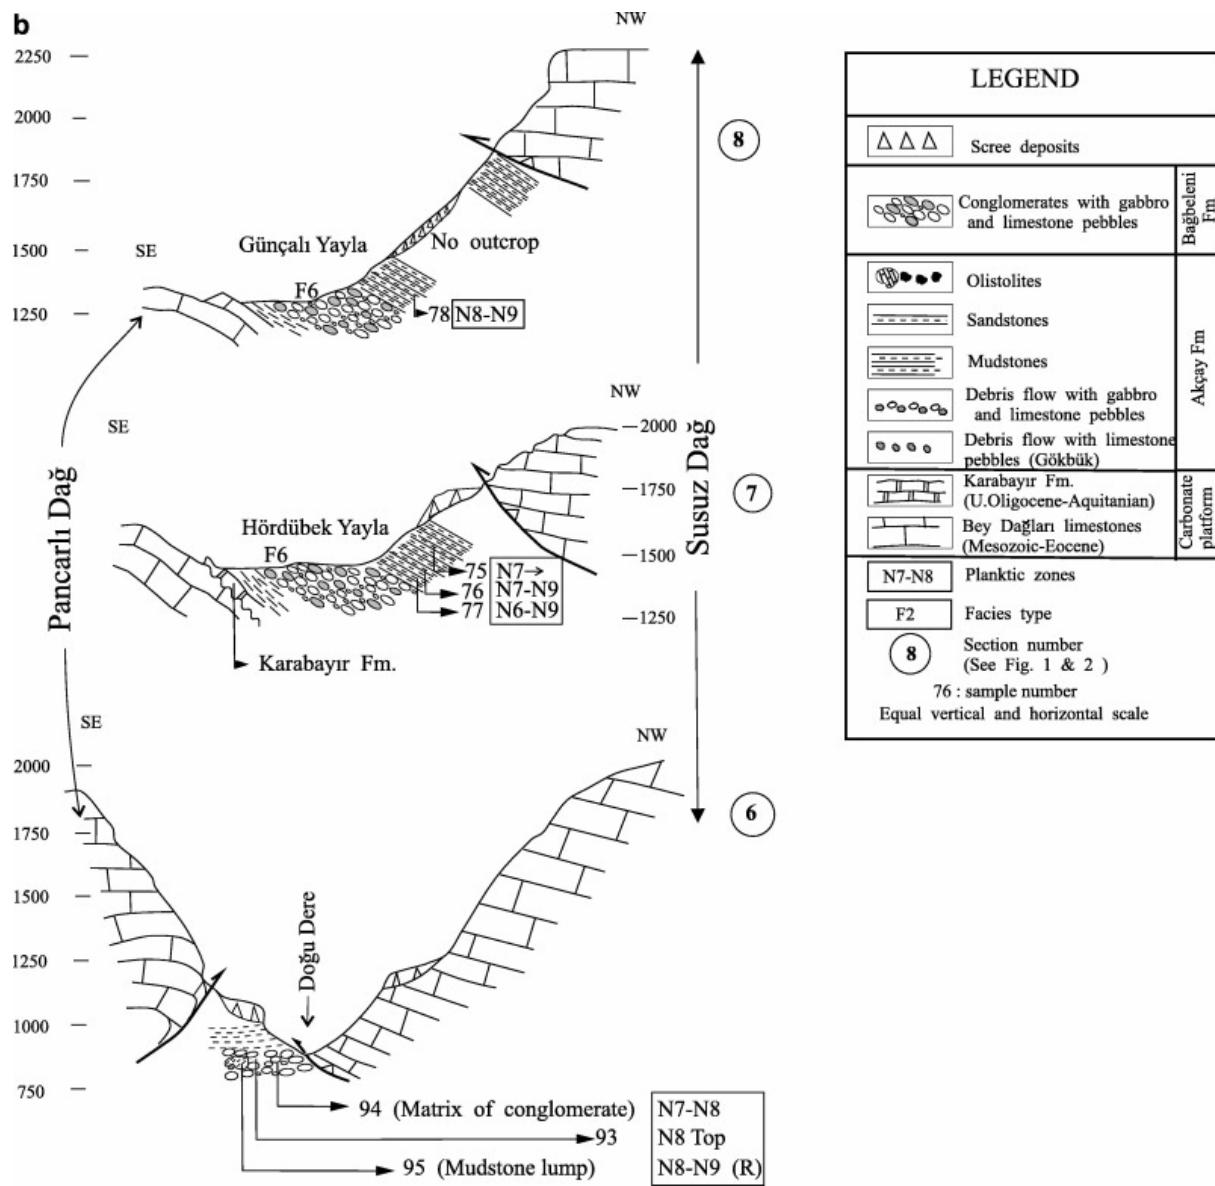

Fig. 4. (a, b) Eight cross-sections through the Çatallar Basin and the Başkoz corridor (see Fig. 1 and Fig. 2 for locations). The northern part of the Çatallar Basin is hidden below the Susuzdağ Thrust. Fossil content of samples is given in Table 2.

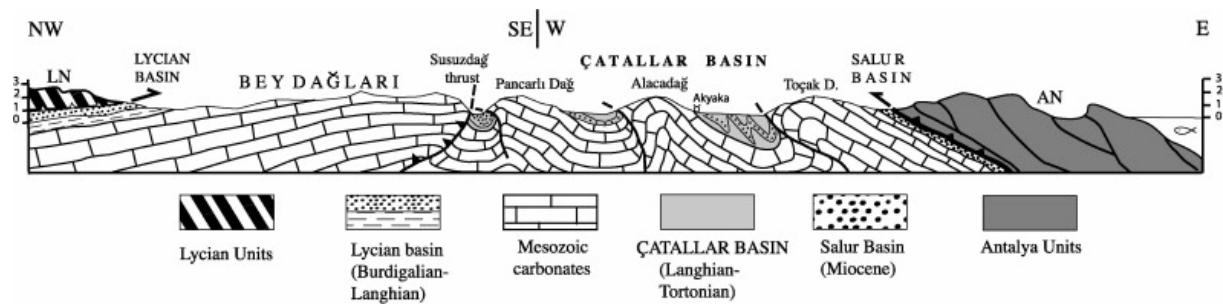

Fig. 5. Schematic cross-section from the Lycian Nappes to the Antalya Nappes (see Fig. 1 for location) showing the intermediate position of the Çatallar Basin and the Late Miocene imbrications of the Bey Dağları platform carbonates.

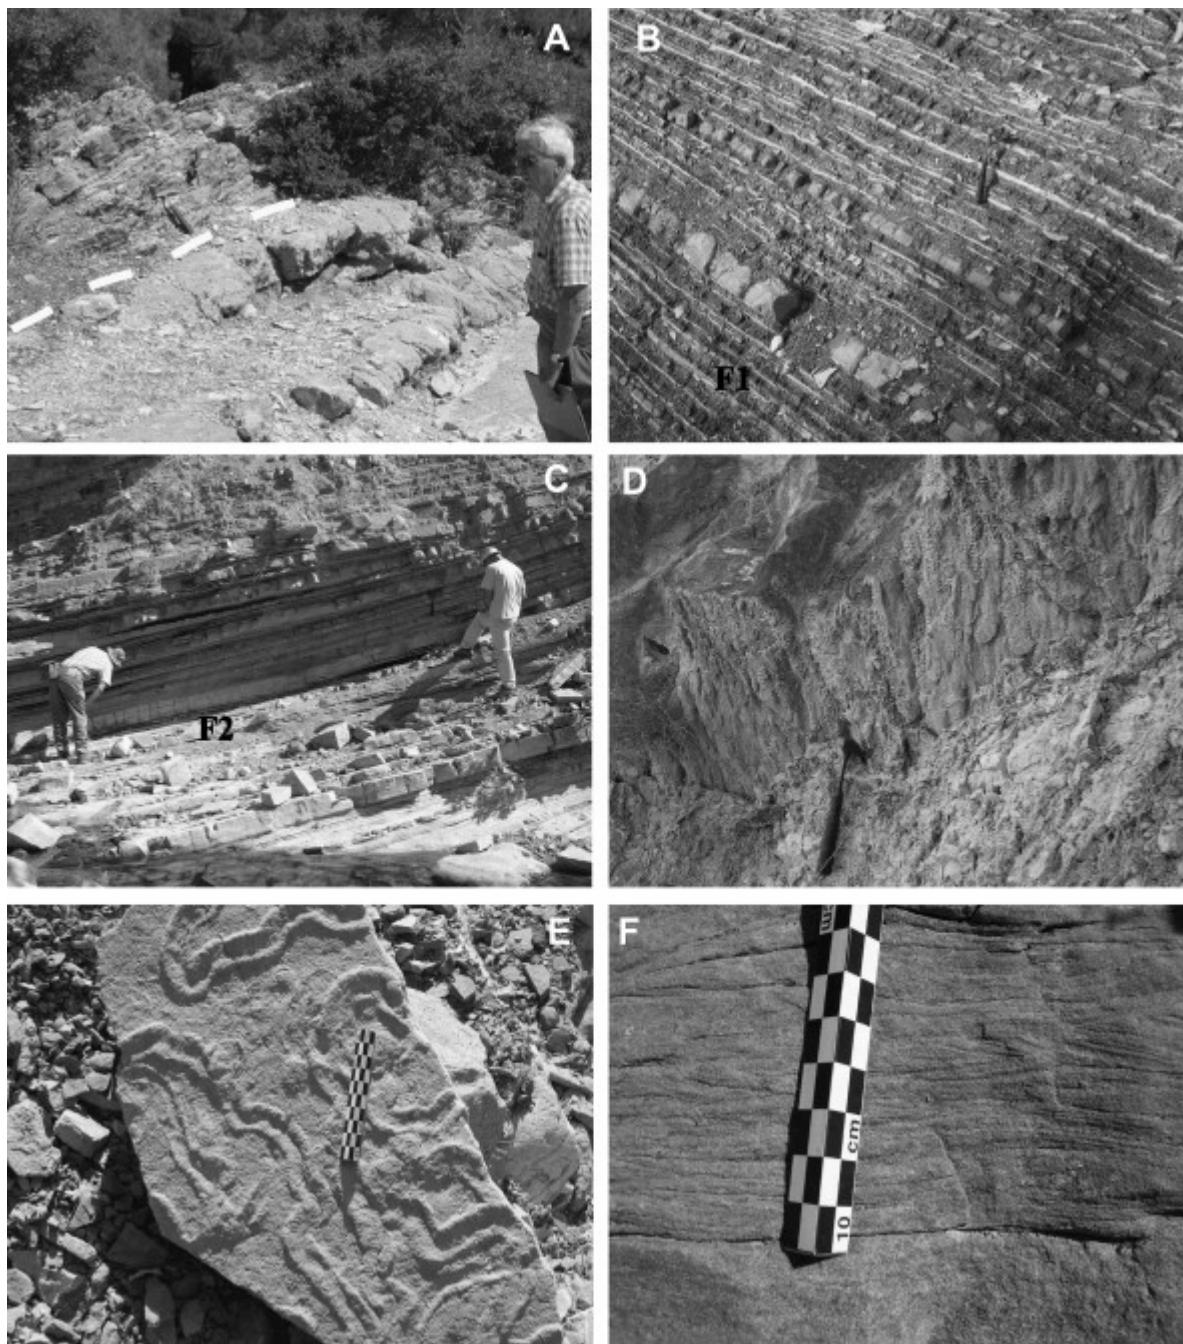

Fig. 6. (A) Field view of algal limestones of the Karabayır formation (Aquitanian) unconformably overlying Upper Cretaceous pelagic limestones. The dash line shows the boundary (location on Fig. 4a, section 2). (B) Field view of facies F1 showing alternating mudstone–sandstones and micritic carbonates. Hammer for scale. (C) General appearance of facies F2 with siltstone-fine sandstone alternations. (D) Flute casts developed under the calcareous sandstone beds. (E) Trace fossils on top of a calcareous sandstone bed. (F) Fine ripples developed on top of calcareous sandstone (Bouma Tc division).

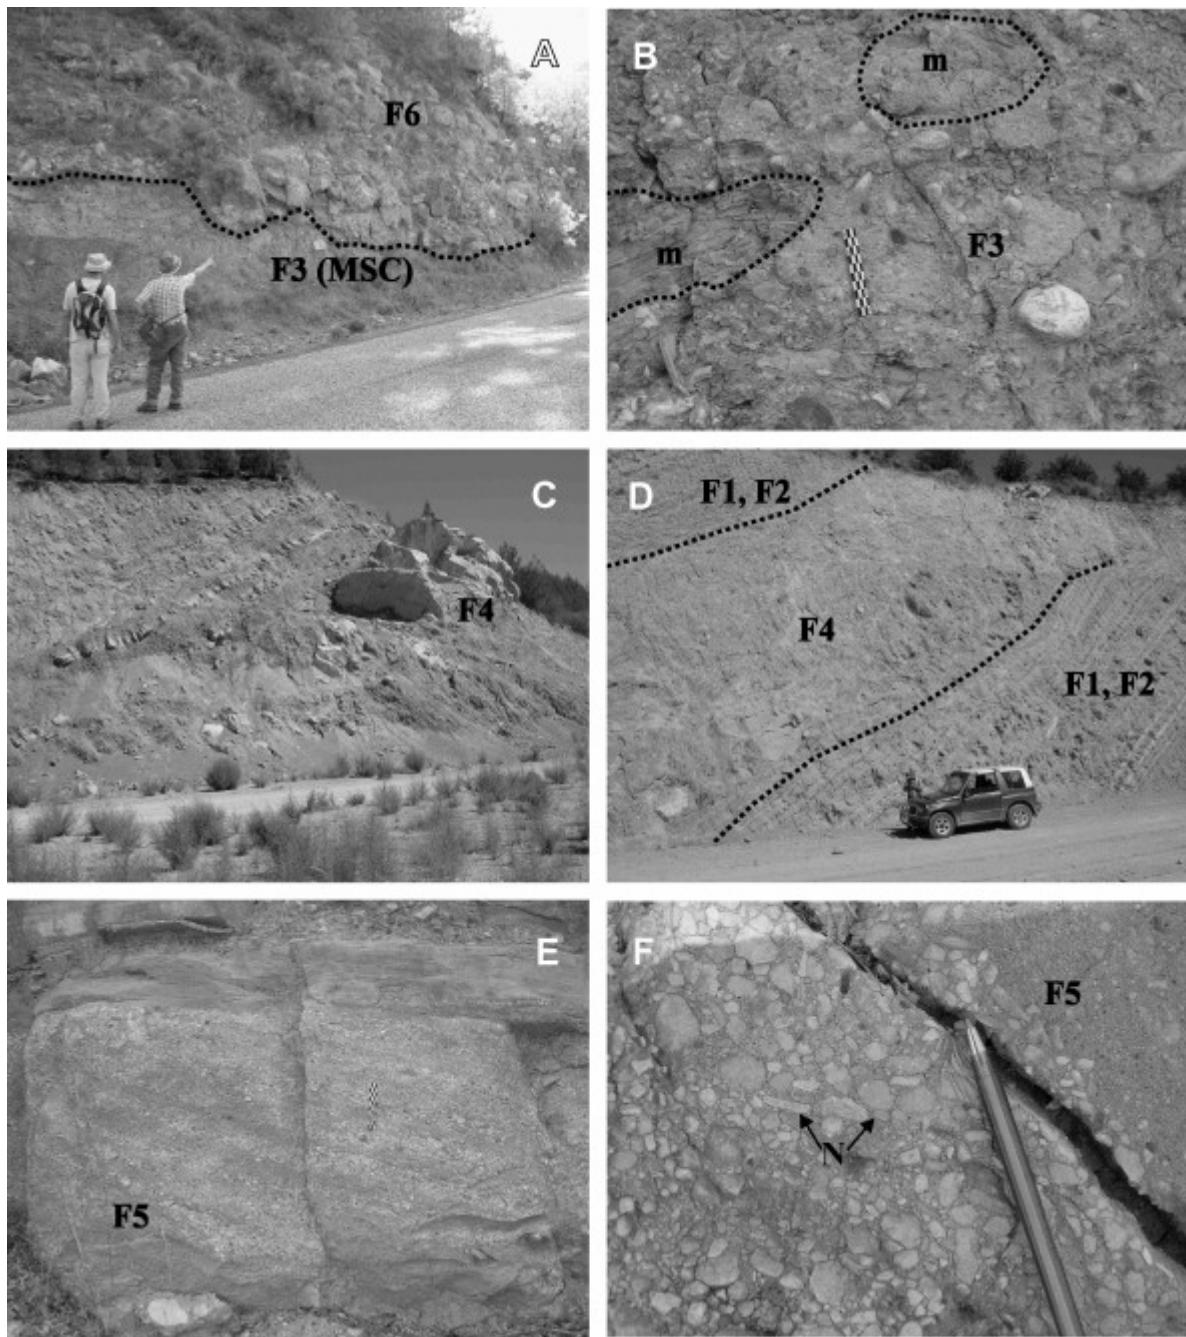

Fig. 7. (A) Field view of a matrix-supported conglomerate (MSC) facies F3 (Fig. 4a, section 5). The black line indicates the boundary with the overlying channelized clast-supported conglomerates (F6). (B) Close-up view of the pebbles and reworked mudstone fragments (m) floating in a sandy matrix (F3) (same locality). Scale is 10 cm long. (C) Field view of a limestone olistolite (F4) (Fig. 4a, section 2). (D) Limestone and ophiolitic blocks together with reefal pebbles (F4) sandwiched between sandstone-siltsone alternations (F2) (Fig. 4a, section). (E) Field view of the carbonate breccia facies F5 showing well-developed cross bedding. The scale in the centre is 10 cm long. (F) Grain supported limestone breccia with reworked Nummulites (N).

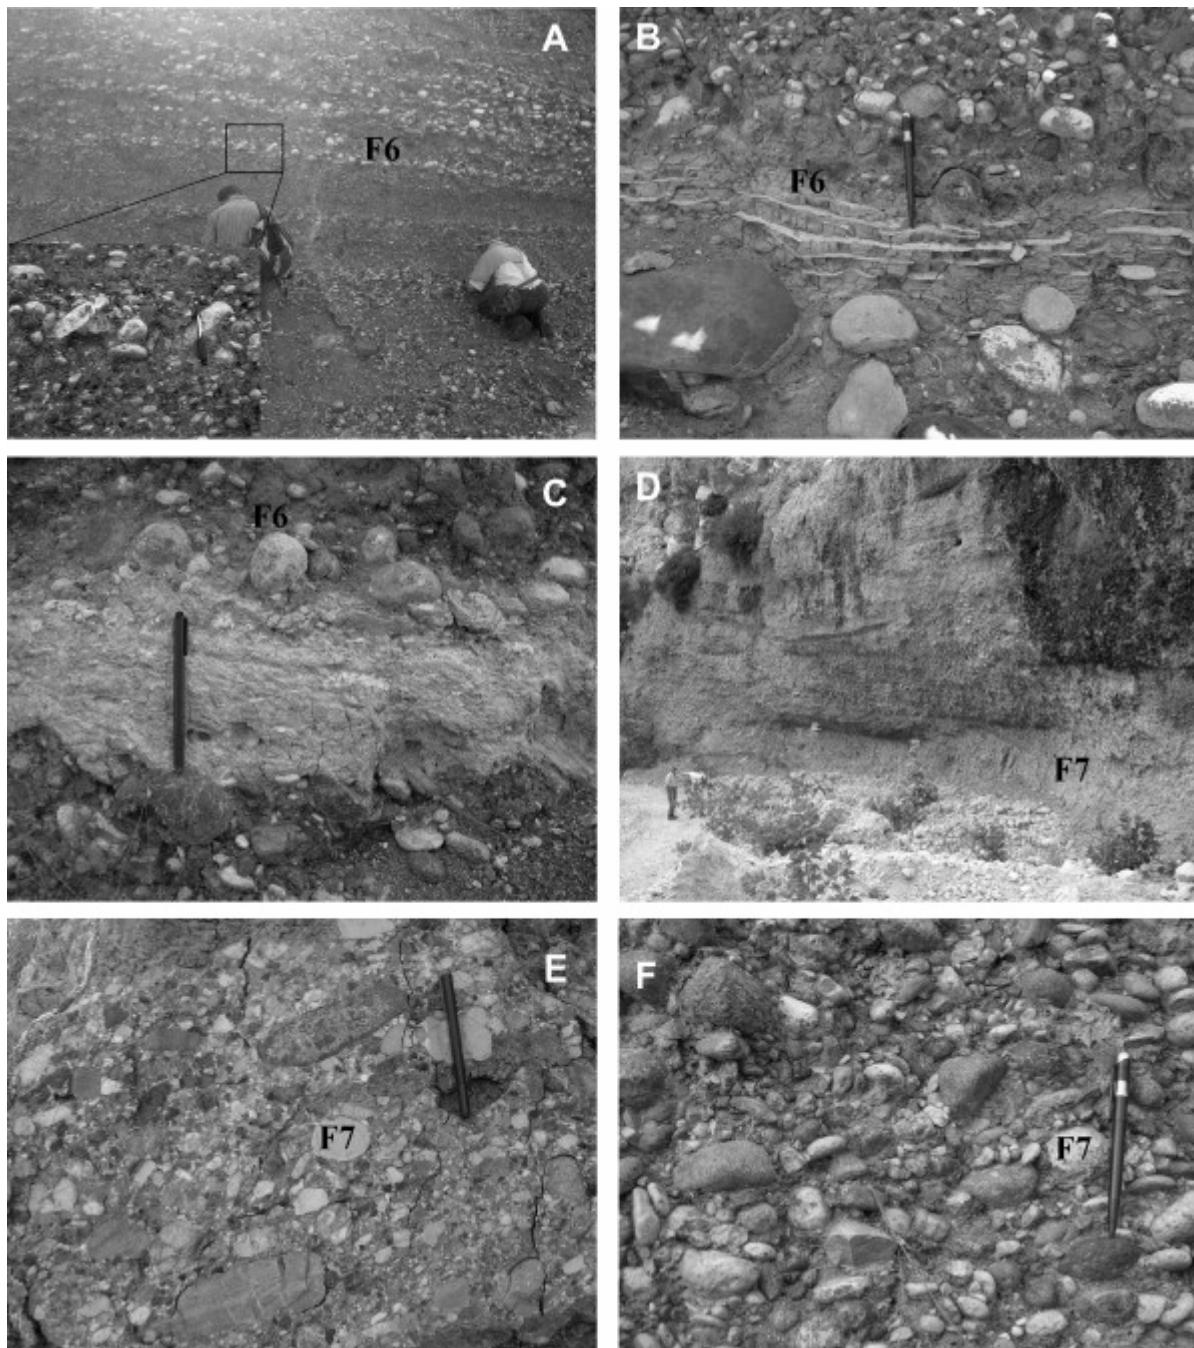

Fig. 8. (A) Imbrications in clast- to matrix-supported conglomerates (F6). The blow up picture at the bottom left corner clearly shows a paleocurrent direction from left to the right (Fig. 4a, section). (B) Red colored fluvial conglomerates (F6). Impersistent white calcrete layers indicate the development of paleosols in a relatively dry environment (same locality). (C) Thicker calcrete beds within the conglomeratic levels (20 cm pencil for scale) (same locality). (D) Field views of the clast-supported conglomerate (F7) with poorly developed large-scale trough cross beds. (Fig. 4a, section 2). (E-F) Rounded radiolarite, gabbro, and basalt, and limestone pebbles showing faint imbrications (same locality).

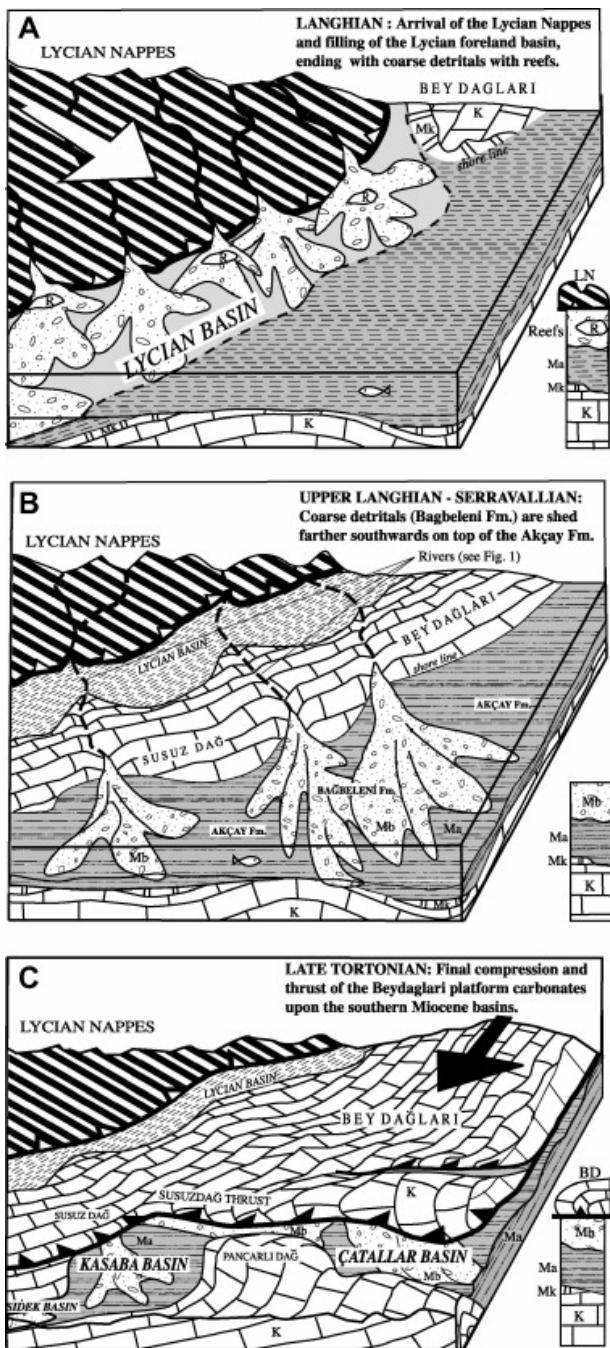

Fig. 9. Schematic evolution of the southern Bey Dağları area, from Langhian to Tortonian. (A) Langhian: in front of the advancing Lycian Nappes, the Lycian foreland basin is filled and ends with coarse detritals (fan deltas) with reefs (R). Farther away, most of the undeformed Bey Dağları platform is overlain by fine detritals (Ma, Akçay formation in the Çatallar Basin) overlying the Karabayır formation (Mk). Trap: local sediment depositional area. (B) Late Langhian and Serravallian: the Lycian Nappes, the Lycian Basin and most of the Bey Dağları platform are emerged and partly eroded. Shallow-marine to subaerial coarse detritals (Mb, Bagbeleni formation) coming from the north are shed southeastwards on top of the Akçay formation. (C) Late Tortonian: Late Miocene to Pliocene thrusts and folds within the Bey Dağları platform delineate the present shape of the Neogene basins, and hide the northern part of the Çatallar Basin under the Susuzdağ Thrust.

## Tables

Table 1. : Description of facies F1 to F7, and their environmental interpretation

Facies	Description	Suggested processes and environment of deposition
F1: Green mudstone-calcareous sandstone-carbonate alternations	<p>Thin- to thick-bedded laterally continuous, massive to faintly-laminated mudstone alternating with very thin micritic carbonates (Fig. 6B). Few cm to dm thick fine- to medium-grained calcareous siltstone-sandstone beds with rare flute casts and current ripples.</p> <p>Sandstone to mudstone ratio is about 1:6. Sandstone beds have sharp to wavy bases and tops with occasional very faint normal grading.</p> <p>Sandstones include red algae, foraminifera, echinoderms and bryozoa fragments. Organic material and abundant planktic foraminifera in the mudstones. 1-3 cm thick white to beige micritic carbonate beds show sharp contacts with the underlying mudstones. Mostly laterally continuous beds but some pinch out within short distances owing to boudinage</p>	<p>Sedimentation largely from suspension in quiet offshore marine environment. Sandy intercalations and flute casts, represent low-density turbidity currents triggered by either storms or tectonic instability (Pickering et al., 1986). Carbonates alternating with mudstones (or marls) reflect rhythmic climate variations or self-organized diagenesis ([Alonso-Zarza and Calvo, 2000] and [Westphal et al., 2004])</p>
F2: Parallel stratified calcareous sandstone-siltstone alternations	<p>Mudstone-siltstone and fine- to medium-grained calcareous sandstone (5–50 cm to 1 m thick) alternations (Fig. 6C). Frequent amalgamation of thickening up sandstone beds. Flat to irregular bases and up to 10 cm long flute and groove casts and large load casts in some beds (Fig. 6D). Planar to wavy bed tops with lingoid ripples and vertical but mostly horizontal burrows on the upper surfaces (Fig. 6E). Mostly massive beds with occasional Bouma divisions of Ta and Tb and abundant Tc and Td (Fig. 6F). Some water escape and slump structures and sand dykes.</p> <p>Well-rounded sandstone grains and often broken fragments of benthic and planktonic foraminifers</p>	<p>Rapid deposition from highly concentrated turbidity currents, followed by deposition from suspension fall-out during “normal” quiet-water conditions after the density flow event (Bouma, 1962).</p> <p>Thick turbiditic deposits record active erosional processes in the backland due to tectonic events accompanied by an active subsidence in the basin. Post depositional deformation, and synsedimentary instability are inferred from water escape and slump structures</p>

Facies	Description	Suggested processes and environment of deposition
	(biocalcarene). 1 to 15 cm thick, green to grey colored mudstone intervals with Lepidocytyines, Amphistegines, Miogypsina and Bryozoa. Few laterally discontinuous, 3-5 cm thick, plant debris accumulations	
F3: Matrix-supported conglomerate	<p>Massive, thickly bedded (1–3 m) and poorly sorted conglomerate composed of pebbles floating in a sandy–muddy matrix (Fig. 7A). Tabular to lenticular beds bounded by flat bases and irregular to wavy tops, laterally thinning away in several tens of meters. Grey to yellow and sometimes red matrix composed of varying mixtures of sand and clay-sized material. Clast-matrix ratio varies locally but is generally around 1:5. Polygenic and disorganized conglomerate with no apparent clast fabric. Sub- to well rounded 1–2 cm to 10–15 cm sized unsorted clasts. Reworked mudstone fragments containing abundant planktic foraminifera (Fig. 7B). Few crudely developed normal to inverse grading</p>	<p>Deposition in subaerial (associated with red matrix) to subaqueous (associated with foraminifera bearing reworked grey mudstone) cohesive debris-flows in various parts of a fan delta. The matrix-supported framework, the absence of sedimentary structures and fabrics indicate gravity-induced deposition en masse. Clayey matrix and clasts floating within the beds indicate rapid deposition from high-viscosity flows with matrix strength ([Enos, 1977], [Nemec and Steel, 1984] and [Nemec and Postma, 1993])</p>
F4: Olistostromes	<p>Chaotic mixture of large isolated blocks (olistoliths) embedded into mudstone to fine-grained deposits with occasional evidence of deformed beds underneath. The different lithologies of the blocks imply various source areas. In a lower olistostrome near Gökbük (see map Fig. 2), the olistoliths are exclusively calcareous, among which reef fragments (probably Aquitanian) and Cretaceous blocks are predominant. The largest blocks, up to 60 m high, made of late Cretaceous wackestones with planktonic organisms and Eocene nummulitic packstones are conspicuous south of Çatallar village, along the road to Finike</p>	<p>Very large isolated blocks (olistoliths) classically represent rock falls (Pickering et al., 1986), and are possibly related to failure of active fault scarps that existed nearby, although none has been identified in the Çatallar Basin yet. They strongly suggest a proximal origin. In contrast, pebbles floating in the muddy–sandy matrix are interpreted as debris-flows (olistostrome), coming from a more distant source. They result from downslope mass-transport resedimentation of unconsolidated siliciclastic sediments (Diaz-Martinez, 2007)</p>

Facies	Description	Suggested processes and environment of deposition
	(Fig. 7C). Smaller blocks and sub- to well-rounded ophiolitic pebbles (5–20 cm in diameter) of serpentinite, corals reefs, gabbros and radiolarites are observed in different parts of the basin. The overlying and underlying deposits are generally parallel stratified mudstone-sandstone intercalations classified as facies F1 and F2 (Fig. 7D)	
F5: Breccia	<p>Chaotic assemblages of matrix- to clast-supported breccia consisting of very angular to subrounded, fine- to medium-grained (0.5–3 cm) fragments. Limestone clasts predominate but clasts of ophiolites, quartz, gabbros and radiolarites may be locally abundant. Thin- to thick-bedded (0.5–1 m) and laterally extensive tabular units with sharply defined flat bases and tops. Some local cross-stratified units (Fig. 7E). Clast shapes vary, but blades are common. Occasional normal grading within the clast-supported beds. Red and/or beige fine-grained limestone clasts or red to lime mudstone matrix. The lime mudstone locally contain reworked Eocene benthic foraminifers (<i>Nummulites</i>) (Fig. 7F)</p>	<p>Sub-aerial and sub-aqueous processes and environments of deposition in basin margin colluvial cones. The breccias indicate gravity induced mass transport including rock falls and slides on steep slopes ([Blirka and Nemec, 1998] and [Nemec and Kazancı, 1999]). Lime mudstone with marine fossils represents deposition in a near shore environment. Red matrix-supported breccia indicates a terrestrial origin</p>
F6: Clast- to matrix-supported imbricated conglomerates	<p>Unsorted to poorly sorted clast- to matrix-supported conglomerate forming laterally extensive, few m thick, tabular to broadly lenticular units. Internal horizontal or crudely developed oblique bedding. Some broadly lenticular units consist of tabular low angle and concave up cross-bedded sets eroded by horizontally bedded tabular units. Flat bases with some scouring. Rounded to subangular limestone, radiolarite, gabbro, basalt, and chert clasts (1–3 cm to 8–10 cm). Elongate pebbles show well-defined preferred orientation with their a-axis aligned parallel to the bedding</p>	<p>Subaerial depositional processes resulting from stream floods in a braided stream of an alluvial fan. Well-developed gravel imbrications indicate the presence of tractive currents. Discontinuous red mudstones suggest temporary exposures within the braided channel system rather than a well-developed flood plain. The white carbonate horizons represent caliche or calcrete, a layer of hard paleosol encrusted with calcium carbonate occurring in arid or semiarid regions. The carbonates that commonly form within soil profiles, and therefore in very superficial settings above the groundwater table,</p>

Facies	Description	Suggested processes and environment of deposition
	<p>plane (Fig. 8A). Very coarse-grained sandstone matrix. Few dm thick and laterally discontinuous red mudstones are locally embedded within the conglomerates. Occasional silt to mud sized, subhorizontal, repetitive white carbonate layers (up to 20 cm thick and couple tens of meters wide) within the red mudstones and conglomerates (Fig. 8B). Few carbonate nodules. Irregular carbonate layers of few m wide and up to 50 cm thick are also observed within the sandy matrix of the conglomerates (Fig. 8C)</p>	<p>are interpreted as pedogenic calcretes (Alonso-Zarza, 2003). The calcrete-bearing paleosols within and/or on top of fluvial deposits probably represent a short period of tectonic quiescence (Capuzzo et al., 1997). The development of carbonates within the matrix of conglomerates might be related to shallow aquifer systems where groundwater calcretes are known to develop (Mann and Horwitz, 1979) especially near the toes of large alluvial fans (Mack et al., 2000)</p>
F7: Clast-supported conglomerate	<p>Disorganized to poorly sorted, clast-supported pebble-cobble conglomerate (Fig. 8D). Very prominent outcrops. Few very thick, laterally extensive red to grey tabular to lenticular beds or large-scale trough cross beds with sharp, locally scoured bases. Subrounded to well rounded, 3–5 cm to 8–10 cm polygenic clasts, with occasional imbrications and some boulders (1 m in diameter). Occasional intergranular coarse-grained sand fills in between pebbles (Fig. 8E and F). Laterally very limited and up to 10 cm thick, coarse-grained sandstone intercalations sporadically occur, but are rapidly cut by the succeeding conglomerate bed. Few reworked mudstone fragments (up to 1 m in diameter) containing abundant planktic foraminifera</p>	<p>Sub-aerial to sub-aqueous processes resulting from hyperconcentrated flows, sheet-flows and/or stream flows. An alluvial fan involving braided stream (Nemec and Postma, 1993) or sheet flood processes (Blair and McPherson, 1994) may account for this facies. A subaqueous environment is also suggested by few wave ripples observed in sandy intercalations and by the presence of reworked mudstone fragments with abundant planktonic foraminifera. Its association with the fossiliferous green mudstone-calcareous sandstone (F1) alternations suggests a proximal fan delta environment</p>

Table 2. : Diagnostic assemblages of planktic foraminifera of selected samples from the Catellar Basin, (see Fig. 4a and b for location)

The complete planktic assemblages of the biozones identified from N7 to N14 are indicated. The chronostratigraphic interpretation is shown in Fig. 3 (gr: group; aff: affinis; cf: confere; sp: species; (R) reworked). Numbers below the table: 1 – Base of the Akçay formation near Akyaka and Çatallar before the arrival of the ophiolitic detritals. 2 – Hördübék and Günçalı Yaylas. 3 – Arif and Başkoz. 4 – Bağbeleni formation near Yalnız. For locations see Fig. 4a and b.
