Abstract—The problem of closed loop system identification in presence of bounded disturbances is considered. In this paper two recursive algorithms are proposed to solve this identification problem. Stability and convergence properties are demonstrated. Simulation results validate the proposed solutions.

I. INTRODUCTION

In recent decades the identification of closed loop systems has received much interest as shown by the following references: [18], [20] [13], [6], [3], [9]. The interest is motivated because for many industrial processes open loop experiments are prohibited (safety, stability, efficiency of operation, etc.) but also for reasons of supervision (the desired performance are met?). All practical identification algorithms have to deal with measurements corrupted by noise and to the best of our knowledge, most of the works in the closed loop identification literature consider the stochastic noise assumption. In some cases (unknown probability distribution of the disturbances, modeling inaccuracy) such assumption cannot be done and the bounded noise assumption seems to be more appropriate.

To address this identification problem we will take inspiration from the identification method CLOE (Closed Loop Output Error) presented in [10], [11] and [12]. This method will be adapted by considering the Set Membership Identification (SMI) algorithms (see [15], [14], [21], [7], [8] and [2]) and particularly the Optimal Bounding Ellipsoid (OBE) algorithms. The computational complexity of these algorithms is low and they are appropriated to handle the identification problem in presence of bounded disturbances. Their principle consists in the estimation of a feasible set of parameters which must be consistent with the measurement data and the model structure. Important contributions have been presented in [5], [4], [1] and [19]. The paper will focus on the extension of some stability and convergence results ([1], [19], [16]) to closed loop output error model.

The paper is organized as follows: in section II the identification problem is posed. In section III, recursive estimation algorithms are derived and their convergence analysis is addressed. Some simulation results are given in section IV. Finally, section V concludes the paper.

II. PROBLEM FORMULATION AND NOTATION

Consider the closed loop depicted in Fig. 1 where the plant is a linear system which can be described by the transfer function $G_o(q)$. r_t , u_t and y_t are respectively an exogenous input, the system input and the system output. w_t denotes the output disturbances and $C(q)$ a linear controller. The underlying output behavior is given by:

$$y_t = \frac{G_o(q)}{1 + G_o(q)C(q)} r_t + \frac{1}{1 + G_o(q)C(q)} w_t \quad (1)$$

Here, it is assumed that there exists a discrete time transfer function $G(q)$ stabilizing the closed loop and such that the output y_t is given by

$$y_t = \frac{G(q)}{1 + G(q)C(q)} r_t + v_t \quad (2)$$

where v_t is an unknown and bounded disturbing term (noise measurement, state disturbances, modeling inaccuracy, etc.):

$$v_t = \left(\frac{G_o(q)}{1 + G_o(q)C(q)} - \frac{G(q)}{1 + G(q)C(q)} \right) r_t + \frac{1}{1 + G_o(q)C(q)} w_t$$

We assume that an upper bound is supposed to be available on v_t :

$$|v_t| \leq \delta_{v_t} \quad (3)$$

The model $G(q)$ is defined by

$$G(q) = q^{-d} \frac{B(q)}{A(q)} \quad (4)$$

with

$$\begin{cases} B(q) = b_0 + b_1 q^{-1} + \dots + b_{n_b} q^{-n_b} \\ A(q) = 1 + a_1 q^{-1} + \dots + a_{n_a} q^{-n_a} \end{cases}$$

and the identification problem treated in this paper is stated as: estimate the parameters $\{b_i\}$ and $\{a_i\}$ of the model by using the available data $\{r_t, y_t\}$, the knowledge of the controller $C(q)$ and the upper bound δ_{v_t} .

The presented identification algorithms are similar to the CLOE algorithm described in [10], [11] and [12]. Here, the difference lies in the nature of the noise component: the noise is not modeled as a stochastic process, the only information is the known upper bound δ_{v_t} . This will have a strong impact on the stability analysis.

Fig. 1. Closed loop system

The one-step-ahead output predictor is defined bearing in mind the optimal predictor structure (see [13]), namely

$$\hat{y}_t = y_t - v_t = \phi_t^T \theta^*$$

with

$$\theta^{*T} = (a_1 \quad \dots \quad a_{n_a} \quad b_0 \quad \dots \quad b_{n_b})$$

$\theta^* \in \mathbb{R}^n$ is the unknown parameters vector to be identified with $n = n_a + n_b + 1$ the number of parameters.

ϕ_t is defined by

$$\phi_t^T = (-\hat{y}_{t-1} \quad \dots \quad -\hat{y}_{t-n_a} \quad \hat{u}_{t-d} \quad \dots \quad \hat{u}_{t-d-n_b})$$

where

$$\hat{u}_t = r_t - C(q)\hat{y}_t$$

and

$$C(q) = \frac{R(q)}{S(q)}$$

A key observation is that the output predictor $\hat{y}_t$ is not linear in the system parameters, this will determine the stability of the identification algorithm.

III. IDENTIFICATION ALGORITHMS

A. The CLOE-OBE (Closed Loop Output Error - OBE) algorithm.

This paper focuses on the design of a recursive identification algorithm for the system described by (2), (3) and (4). Before introducing the parameter adaptation algorithm, let us define the well known a priori and a posteriori predictors as

$$\begin{cases} \hat{y}_{t/t-1} = \hat{\phi}_{t-1}^T \hat{\theta}_{t-1} \\ \hat{y}_{t/t} = \hat{\phi}_t^T \hat{\theta}_t \end{cases}$$

$\hat{\theta}_t$ represents the estimation of the parameters vector at the actual time t while $\hat{\phi}_t$ is an estimate of the prediction data vector ϕ_t which is simply obtained by replacing the unknown components $\hat{y}_{t-i}$ by their a posteriori estimates $\hat{y}_{t-i/t-i}$ and $\hat{u}_{t-d-i}$ by their a posteriori estimates $\hat{u}_{t-d-i/t-d-i}$:

$$\hat{\phi}_t^T = (-\hat{y}_{t-1/t-1} \quad \dots \quad -\hat{y}_{t-n_a/t-n_a} \quad \hat{u}_{t-d/t-d} \quad \dots \quad \hat{u}_{t-d-n_b/t-d-n_b})$$

with

$$\hat{u}_{t-i/t-i} = r_{t-i} - C(q)\hat{y}_{t-i/t-i}$$

Fig. 2. Closed loop identification scheme

From these adjustable predictors we get the following closed loop a priori and a posteriori prediction errors:

$$\begin{cases} \epsilon_{t/t} = y_t - \hat{y}_{t/t} \\ \epsilon_{t/t-1} = y_t - \hat{y}_{t/t-1} \end{cases}$$

A key observation is that the a posteriori prediction error $\epsilon_{t/t}$ can be expressed as:

$$\begin{aligned} \epsilon_{t/t} &= y_t - \hat{\phi}_t^T \hat{\theta}_t \\ \epsilon_{t/t} &= \phi_t^T \theta^* + v_t - \hat{\phi}_t^T \hat{\theta}_t + (\hat{\phi}_t^T \theta^* - \hat{\phi}_t^T \theta^*) \end{aligned}$$

Bearing in mind structures of ϕ_t and $\hat{\phi}_t$ this gives

$$\epsilon_{t/t} = \frac{S(q)}{A(q)S(q) + q^{-d}B(q)R(q)} \hat{\phi}_t^T \tilde{\theta}_t + v_t \quad (5)$$

with $\tilde{\theta}_t = \theta^* - \hat{\theta}_t$.

It will be seen later that this relationship is fundamental for establishing the stability and convergence properties of the identification algorithm.

The estimated parameters vector $\hat{\theta}_t$ has to maintain the closed loop output error below a bound defined from the upper bound on the disturbance v_t . Under some conditions presented below, the following Closed Loop Output Error - OBE algorithm provides such estimation:

$$\begin{cases} \hat{\theta}_t = \hat{\theta}_{t-1} + \Gamma_t \epsilon_{t/t-1} \\ \Gamma_t = \frac{P_{t-1} \hat{\phi}_t \sigma_t}{\lambda + \hat{\phi}_t^T P_{t-1} \hat{\phi}_t \sigma_t} \\ P_t = \frac{1}{\lambda} (I_n - \Gamma_t \hat{\phi}_t^T) P_{t-1} \\ \epsilon_{t/t-1} = y_t - \hat{\phi}_t^T \hat{\theta}_{t-1} \end{cases} \quad (6)$$

where $0 < \lambda \leq 1$ is a design parameter forgetting factor that will be used to monitor the parameter adaptation dynamics. σ_t is a switching flag given by:

$$\sigma_t = \begin{cases} \frac{\lambda}{\hat{\phi}_t^T P_{t-1} \hat{\phi}_t} \left(\left| \frac{\epsilon_{t/t-1}}{\delta_t} \right| - 1 \right) & \text{if } (|\epsilon_{t/t-1}| > \delta_t) \text{ and } (\hat{\phi}_t^T P_{t-1} \hat{\phi}_t > 0) \\ 0 & \text{otherwise} \end{cases} \quad (7)$$

δ_t is a user defined positive scalar.

From (6) the a posteriori prediction error $\varepsilon_{t/t}$ can be written as

$$\varepsilon_{t/t} = (1 - \hat{\phi}_t^T \Gamma_t) \varepsilon_{t/t-1}$$

which can also be rewritten, by using the expression for Γ_t , as:

$$\varepsilon_{t/t} = \frac{\lambda}{\lambda + \hat{\phi}_t^T P_{t-1} \hat{\phi}_t} \varepsilon_{t/t-1} \quad (8)$$

Using the value of σ_t for $\sigma_t \neq 0$ (8) yields:

$$|\varepsilon_{t/t}| = \delta_t$$

Provided that the persistent excitation condition is satisfied (i.e. $\hat{\phi}_t^T P_{t-1} \hat{\phi}_t > 0$), this clearly shows that the CLOE-OBE algorithm ensures the following key property:

$$\begin{cases} \text{if } |\varepsilon_{t/t-1}| > \delta_t \text{ then } \sigma_t \neq 0 \text{ and } |\varepsilon_{t/t}| = \delta_t \\ \text{if } |\varepsilon_{t/t}| \leq \delta_t \text{ then } \sigma_t = 0 \text{ and } |\varepsilon_{t/t}| \leq \delta_t \end{cases}$$

δ_t is then a bound on the a posteriori adaptation error which has to be specified taking into account the bound δ_{v_t} .

The results of the stability analysis are presented in the following theorem. These results are similar to the stability analysis of the Output Error - OBE algorithm used for plant model identification in open loop and presented in [16].

Result 1: Consider the class of systems defined in section II and the CLOE-OBE algorithm given by (6) and (7). Assume that

- $G(q)$ is such that

$$\left\| 1 - \frac{A(q)S(q) + q^{-d}B(q)R(q)}{S(q)} \right\|_1 < 1 \quad (9)$$

where $\|\cdot\|_1$ is the l_1 induced norm;

- δ_t is such that:

$$\delta_t \geq \frac{\left\| \frac{A(q)S(q) + q^{-d}B(q)R(q)}{S(q)} \right\|_1}{1 - \left\| 1 - \frac{A(q)S(q) + q^{-d}B(q)R(q)}{S(q)} \right\|_1} \delta_{v_t} \quad (10)$$

then for all initial conditions

$$|\tilde{\theta}_t|^2 \leq \gamma_1 |\tilde{\theta}_0|^2 \quad (11)$$

$$\text{with } \gamma_1 = \frac{\lambda_{\max}(P_0^{-1})}{\lambda_{\min}(P_0^{-1})}.$$

where $\lambda_{\max}(P_0^{-1})$ and $\lambda_{\min}(P_0^{-1})$ are respectively the maximum and the minimum eigenvalues of P_0^{-1} .

If, furthermore, $\{\hat{\phi}_t\}$ is a persistently exciting sequence of order $o_e \geq n$, i.e there exist $\alpha > 0$ and $\beta > 0$ such that for all t

$$\alpha I_n \leq \sum_{i=0}^{o_e-1} \hat{\phi}_{t+i} \sigma_{t+i} \hat{\phi}_{t+i}^T \leq \beta I_n \quad (12)$$

Then the following properties hold:

- for all $t \geq o_e + 1$

$$|\tilde{\theta}_t|^2 \leq \gamma_2 \lambda^t |\tilde{\theta}_0|^2 \quad (13)$$

with

$$\gamma_2 = \begin{cases} \frac{\lambda_{\max}(P_0^{-1})}{\alpha} \left(\frac{\lambda^{-o_e} - 1}{\lambda^{-1} - 1} \right) & \text{if } \lambda < 1 \\ \frac{\lambda_{\max}(P_0^{-1})}{\alpha} & \text{if } \lambda = 1 \end{cases}$$

- For $\lambda < 1$ one has

$$\lim_{t \rightarrow \infty} |\varepsilon_{t/t-1}| \leq \delta_t \quad (14)$$

Proof: For lack of space we do not detail the proof. The form of the adaptation algorithm and the relation (5) between $\varepsilon_{t/t}$ and $\tilde{\theta}_t$ allows to use results established in [16].

In a first part of the proof, it is shown that the Lyapounov function $V_t = \tilde{\theta}_t^T P_t^{-1} \tilde{\theta}_t$ is such that $V_t \leq \lambda^t V_0$ if conditions (9) and (10) are satisfied.

In a second part property (11) is obtained using the fact that $P_t^{-1} \geq \lambda^t P_0^{-1}$. Finally, the persistent excitation condition is used to get an other bound on P_t^{-1} , this gives properties (13) and (14). ■

Remark 1: The conditions (9) and (10) are only sufficient conditions and we have observed the algorithm to work well in some cases where these conditions are not satisfied.

Remark 2: The condition (9) implies the asymptotic stability of the controller used during the identification step.

Remark 3: The ability to reach the true parameters vector depends on the threshold δ_t , thus its specification proves to be particularly crucial. The design of this threshold is influenced by the system throughout the polynomials $A(q)$ and $B(q)$ (which are unknown objects), by the controller and by the disturbances effects throughout the bound δ_{v_t} . A dichotomy-based procedure could be used to get an appropriate value for δ_t using all the a priori knowledge on the system. In the next subsection a modified algorithm is proposed to relax conditions (9) and (10).

B. The F-CLOE-OBE (Filtered - CLOE-OBE) algorithm.

Here the idea is to remove the condition (9) required for stability, to this end we use an adaptation filter $F(q)$. Let first define the a priori and a posteriori adaptation errors as

$$\begin{cases} \eta_{t/t-1} = \varepsilon_{t/t-1} + (F(q) - 1) \varepsilon_{t/t} \\ \eta_{t/t} = F(q) \varepsilon_{t/t} \end{cases}$$

$F(q)$ is a monic adaptation filter designed by the user. These definitions allow us to propose a filtered parameter adaptation algorithm by simply substituting in (6) and (7):

- $\varepsilon_{t/t-1}$ by $\eta_{t/t-1}$ and $\varepsilon_{t/t}$ by $\eta_{t/t}$;
- y_t by $\underline{y}_t^F$ such that $F(q)y_t^F = y_t$ and $\hat{\phi}_t$ by $\hat{\phi}_t^F$ such that $F(q)\hat{\phi}_t^F = \hat{\phi}_t$.

The idea is to compensate the effect of $\frac{S(q)}{A(q)S(q)+q^{-d}B(q)R(q)}$ in (9) and (10).

Taking into account these adjustments, the two following equations sets summarize the proposed Filtered CLOE-OBE algorithm:

$$\begin{cases} \hat{\theta}_t = \hat{\theta}_{t-1} + \Gamma_t \eta_{t/t-1} \\ \Gamma_t = \frac{P_{t-1} \hat{\phi}_{t-1}^F \sigma_t}{\lambda + \hat{\phi}_{t-1}^F P_{t-1} \hat{\phi}_{t-1}^F \sigma_t} \\ P_t = \frac{1}{\lambda} \left(I_n - \Gamma_t \hat{\phi}_{t-1}^F \right) P_{t-1} \\ \varepsilon_{t/t-1} = y_t^F - \hat{\phi}_{t-1}^F \hat{\theta}_{t-1} \end{cases} \quad (15)$$

with

$$\sigma_t = \begin{cases} \frac{\lambda}{\hat{\phi}_{t-1}^F P_{t-1} \hat{\phi}_{t-1}^F} \left(\left| \frac{\eta_{t/t-1}}{\delta_t} \right| - 1 \right) \\ \text{if } (|\eta_{t/t-1}| > \delta_t) \text{ and } \left(\hat{\phi}_{t-1}^F P_{t-1} \hat{\phi}_{t-1}^F > 0 \right) \\ 0 \text{ otherwise} \end{cases} \quad (16)$$

It can easily be established that if the persistent excitation condition is satisfied then the following key property holds:

$$\forall \sigma_t \quad |\eta_{t/t}| \leq \delta_t$$

bearing in mind that δ_t is a now a bound on the a posteriori adaptation error $\eta_{t/t}$.

Here the equation of the a posteriori prediction error is:

$$\varepsilon_{t/t} = \frac{S(q)}{A(q)S(q) + q^{-d}B(q)R(q)} \hat{\phi}_{t-1}^F \tilde{\theta}_t + \frac{1}{F(q)} v_t$$

which gives

$$\eta_{t/t} = F(q) \frac{S(q)}{A(q)S(q) + q^{-d}B(q)R(q)} \hat{\phi}_{t-1}^F \tilde{\theta}_t + v_t$$

Using this last equation, the following result presents an analysis of the proposed F-CLOE-OBE algorithm.

Result 2: Consider the class of systems defined in section II and the F-CLOE-OBE algorithm given by (15) and (16). Assume that $F(q)$ and $G(q)$ are such that

$$\left\| 1 - \frac{A(q)S(q) + q^{-d}B(q)R(q)}{S(q)} \frac{1}{F(q)} \right\|_1 < 1 \quad (17)$$

• δ_t is such that:

$$\delta_t \geq \frac{\left\| \frac{A(q)S(q) + q^{-d}B(q)R(q)}{S(q)} \frac{1}{F(q)} \right\|_1}{1 - \left\| 1 - \frac{A(q)S(q) + q^{-d}B(q)R(q)}{S(q)} \frac{1}{F(q)} \right\|_1} \delta_{v_t} \quad (18)$$

then for all initial conditions

$$|\tilde{\theta}_t|^2 \leq \gamma_1 |\tilde{\theta}_0|^2 \quad (19)$$

If, furthermore, $\{\hat{\phi}_t^F\}$ is a persistently exciting sequence of order $o_e \geq n$, then the following properties hold:

• for all $t \geq o_e + 1$

$$|\tilde{\theta}_t|^2 \leq \gamma_2 \lambda^t |\tilde{\theta}_0|^2 \quad (20)$$

• For $\lambda < 1$ one has

$$\lim_{t \rightarrow \infty} |\eta_{t/t-1}| \leq \delta_t \quad (21)$$

Proof: The proof of this result follows the same scheme that the proof of result 1, the difference lies in the relation between $\eta_{t/t}$ and $\tilde{\theta}_t$. ■

The ideal filter is $F(q) = \frac{A(q)S(q) + q^{-d}B(q)R(q)}{S(q)}$. Thus, conditions (17) and (18) are much milder than conditions (9) and (10) if a reasonable estimated model is available. This remark leads to the following iterative identification scheme:

- 1) Choose a high threshold δ_t and apply the CLOE-OBE algorithm to get $\hat{G}(q)$;
- 2) Given this first estimation, design a filter

$$F(q) = \frac{\hat{A}(q)S(q) + q^{-d}\hat{B}(q)R(q)}{S(q)}$$

and choose a lower δ_t ;

- 3) Apply the F-CLOE-OBE algorithm to get a new $\hat{G}(q)$;
- 4) Repeat steps 2 and 3 until convergence of step 3.

The first step is an initialization step: an initial estimate of the model is necessary so as to implement this F-CLOE-OBE algorithm. It is difficult to make a general discussion on the behavior of that iterative scheme and no global convergence results are available (not more than for the recursive maximum likelihood algorithm [13]), however it is successfully applied on a numerical example in the next section.

Note that if $F(q) \simeq \frac{A(q)S(q) + q^{-d}B(q)R(q)}{S(q)}$ it is possible to choose $\delta_t = \delta_{v_t}$. In that case, from (21) we have $\lim_{t \rightarrow \infty} \hat{\theta}_t = \hat{\theta}$ where $\hat{\theta}$ is such that

$$|\eta_t| \leq \delta_{v_t}$$

with $\eta_t = F(q)\varepsilon_t = F(q) \left(y_t^F - \hat{\phi}_{t-1}^F \hat{\theta} \right) = y_t - \hat{\phi}_t^T \hat{\theta}$. Then the contribution of the filter $F(q)$ is twofold: it relaxes stability condition of the algorithm and it allows the estimation of a model $\hat{G}(q)$ such that:

$$\left| \left(y_t - \frac{\hat{G}(q)}{1 + \hat{G}(q)C(q)} r_t \right) \right| \leq \delta_{v_t} \quad (22)$$

which is coherent with (2), (3) and (4).

IV. SIMULATION RESULTS

Numerical data have been generated according to (2), (3) and (4). The system and the controller are the following:

$$G_o(q) = \frac{q^{-1} + 0.1q^{-2}}{1 - 1.8q^{-1} + 0.7q^{-2}} \quad C(q) = \frac{0.1}{1 - 0.4q^{-1}}$$

TABLE I
NUMERICAL VALUES OF THE TRUE PARAMETERS AND THE ESTIMATED
PARAMETERS

parameter	$\theta^{(1)}$	$\theta^{(2)}$	$\theta^{(3)}$	$\theta^{(4)}$
real value	$b_0 = 1$	$b_1 = 0.1$	$a_1 = -1.8$	$a_2 = 0.7$
Procedure 1	0.6498	1.2544	-1.4893	0.2952
Procedure 2	0.7412	0.4164	-1.7398	0.6351

Let notice that the plant is unstable and condition (9) in result 1 is violated in this example.

The exogenous input r_t is a random binary sequence of length $N = 4000$. v_t is a noise generated in the following manner:

$$v_t = \delta_{v_t} \frac{1}{2} (e_t + \sin(\pi t/10))$$

where e_t is a white noise uniformly distributed in $[-1; 1]$ and $\delta_{v_t} = 5$ (this corresponds to a signal to noise ratio of 9.12dB). The first half of the data has been used in the estimation step, the second half has been used in the validation step.

It can easily be shown that condition (9) in result 1 is not satisfied in this example. However two identification procedures have been used:

- Procedure 1: even if condition (9) is not satisfied, we can try to use the CLOE-OBE algorithm to identify the system. This is the first identification procedure.
- Procedure 2: this second identification procedure is our iterative scheme. This scheme uses the F-CLOE-OBE algorithm and has been applied over 10 iterations (on this example the time required to obtain the convergence of the estimates).

For each procedure we have chosen the threshold δ_t as follows:

- Procedure 1: $\delta_t = \delta_{v_t}$.
- Procedure 2: δ_t : we have chosen a decreasing threshold.

At iteration i we have

$$\delta_t^{(i)} = \left(\delta_t^{(ini)} - \delta_t^{(fin)} \right) e^{-i} + \delta_t^{(fin)}$$

with $\delta_t^{(ini)} = 5\delta_{v_t}$ and $\delta_t^{(fin)} = \delta_{v_t}$.

The following results correspond to the estimates made on a single data series.

Fig. 3 presents the improvement of the estimated vector at the end of each iteration in the iterative scheme. It appears that the iterative procedure allows a clear convergence of the estimated parameters to their true value. This is confirmed by Fig. 4 which gives the ideal filter $F(q)$ and its successive estimates. Fig. 5 shows the convergence of the estimated models towards the nominal system. Note that on other applications, it is possible that the number of iterations required for convergence is different from 10.

The table I confirms the good performance of the proposed iterative scheme compared to the algorithm CLOE-OBE: the

Fig. 3. Convergence of parameters

Fig. 4. Bode diagrams of ideal filter $F(q) = \frac{A(q)S(q)+q^{-d}B(q)R(q)}{S(q)}$ and its estimates

use of the filter $F(q)$ in the algorithm improve the quality of the estimated parameters. The closeness of the estimated parameters to real parameters depends on the noise level δ_{v_t} . Fig. 6 allows the comparison between $\frac{G_o(q)}{1+G_o(q)C(q)}$ and its estimates $\frac{\hat{G}(q)}{1+\hat{G}(q)C(q)}$ with procedure 1 and procedure 2. One can conclude from these Bode diagrams that the developed iterative method works well.

This is confirmed by Fig. 7 which presents thresholds $\pm\delta_{v_t}$ and the output errors $y_t - \frac{\hat{G}(q)}{1+\hat{G}(q)C(q)}r_t$ for each estimated model (model for procedure 1 and final model for procedure 2 at the 10th iteration). It appears that the model obtained with the iterative scheme using the F-CLOE-OBE is the only one satisfying (22).

V. CONCLUSION

In this study, we have proposed two algorithms allowing the identification of a system operating in closed loop and subject to bounded disturbances. The second algorithm is a filtered adaptation of the first one, the introduced filter is used to relax some sufficient conditions for stability and convergence. Using the second algorithm in an iterative scheme has lead to a significant improvement of the estima-

tion in a numerical example. In terms of perspective, some comparisons with other methods will be presented. Moreover it might be interesting to analyze the set membership of the estimated parameters compared to the true values and it might also be interesting to propose alternative solutions to relax stability and convergence conditions.
