Abstract – The objective of this experiment was to determine the effect of a 5-day progesterone priming prior to a GnRH-PGF$_{2\alpha}$ treatment on reproductive performance of anestrous goats. Thirty-six Mountain Black goats were randomly assigned in a 2×2 factorial arrangement and were administered intravaginally on day –12, either with 300 mg progesterone inserts (CGPE and CGP) or with 0 mg progesterone (GPE and GP) for 5 days. On day –6, the goats were injected with 100 µg GnRH, followed 6 days later by 15 mg PGF$_{2\alpha}$ (day 0), the time at which the goats in the CGPE and GPE groups were administered 300 IU eCG injections and those in CGP and GP groups were administered the control solution. The goats were exposed to four fertile bucks at 0 h and were checked for breeding marks at 6-h intervals for 72 h. Blood samples were collected from all goats for progesterone analysis. Progesterone concentrations increased only in CGPE and CGP during the period of device insertion but remained low in GPE and GP groups ($P < 0.001$). Progesterone levels at the time of GnRH injection on day –6 were basal (0.2 ± 0.04 ng·mL^{-1}) among the groups and began to increase starting on day –2. Day 0 progesterone concentrations differed ($P < 0.05$) among groups and were significantly influenced by CIDR-G ($P < 0.001$). A similar proportion of goats expressed estrus and intervals to detected estrus were shorter ($P < 0.05$) in the CGPE and GPE groups than in GP with no difference between the CGPE, CGP and GPE or between CGP and GP groups. The number of goats ovulating based upon elevated progesterone levels on day 0 was significantly greater ($P = 0.002$) in CGPE (9/9) and CGP (9/9) than GPE (6/9) and GP (5/9) groups and was significantly influenced by CIDR-G ($P = 0.03$). All pregnant goats had elevated progesterone concentration on day 0 and none of the goats with basal progesterone levels became pregnant. Pregnancy and kidding rates, twinning percentage and the number of kids born per goat exposed were greater ($P < 0.05$) among goats treated with progesterone and eCG. In conclusion, progesterone priming and eCG are essential for producing higher rates of pregnancy and kidding in GnRH-PGF$_{2\alpha}$-treated anestrous goats.

estrus synchronization / progesterone priming / GnRH / PGF$_{2\alpha}$ / goats

1. INTRODUCTION

A successful goat enterprise is closely related to the level of kid production. Hormonal treatment for estrus synchronization or induction is effective in increasing the proportion of females that become pregnant. A number of strategies have been used to stimulate and control ovarian activity in goats with the aim of increasing fertility rates. Progesterone-containing inserts combined with eCG at the time of insert withdrawal, is perhaps the most widely used technique [1, 2]. However, low first-cycle conception rate and poor fertility has accompanied progestagen usage in some cases [3–6] and thus, efforts are being made for alternatives. The potential use of GnRH-$PGF_{2\alpha}$ has been reported in cattle [7, 8]. The alteration of ovarian follicular dynamics with GnRH prior to induction of corpus luteum regression with $PGF_{2\alpha}$, improves the precision of estrus response [9, 10]. In sheep, a 4-day progesterone priming was essential for the effectiveness of the GnRH-$PGF_{2\alpha}$ protocol in anestrous ewes [11]. Progesterone priming prevented follicular turnover and maintained large follicles responsive to GnRH and sensitized GnRH-$PGF_{2\alpha}$-treated anestrous ewes [11]. The use of GnRH-$PGF_{2\alpha}$ in progesterone-pretreated goats has not yet been documented. The objective of this experiment was to determine the effect of a 5-day progesterone priming prior to a GnRH-$PGF_{2\alpha}$ treatment with or without eCG on the reproductive performance of anestrous goats.

2. MATERIALS AND METHODS

2.1. Animals

Thirty-six pluriparous anestrous Mountain Black goats, weighing 39.2 ± 0.5 kg, were studied in an experiment conducted at the Agricultural Center for Research and Production at the Jordan University of Science and Technology located in the north-western part of Jordan at 32° 33' N 35° 51' E

and an altitude of 850 m during the months of May and June 2003. All goats had previously kidded at least once with an average litter size of 1.1 kids per doe kidding and 0.9 kid per doe exposed. The goat's last kidding dates ranged from November 15, 2002 to February 1, 2003, and had their kids weaned by May 5, 2003. The goats were fed 1 kg alfalfa hay and 0.5 kg concentrate mixture per goat per day. Trace mineral salt blocks and water were available ad libitum.

2.2. Experimental design

GnRH-$PGF_{2\alpha}$-treated anestrus goats ($n = 36$) were randomly assigned in equal numbers in a 2 × 2 factorial arrangement and were administered intravaginally on May 17 (day –12) with either 300 mg progesterone (CIDR-G, Pharmacia and Upjohn Limited Company, MT Wellington, Auckland) inserts (CGPE and CGP) or 0 mg progesterone (GPE and GP). The inserts were kept in place for 5 days and were removed on May 22 (day –7). Twenty-four hours following insert removal (May 23), the goats were injected i.m. with 100 µg GnRH (Cystorelin, Sanofi Animal Health, Libourne Cedex, France), followed 6 days later by 15 mg $PGF_{2\alpha}$ injection (Lutalyse, Pharmacia & Upjohn n.v./s.a. Puurs, Belgium). Immediately following the $PGF_{2\alpha}$ injection on May 29 (day 0), each goat in the CGPE and GPE groups was administered i.m. with 300 IU eCG injection (Sanofi Animal Health, Libourne Cedex, France) and those in the CGP and GP groups were administered with saline. All goats were run together in a single pen with four fertile bucks whose briskets were painted with white paint. The bucks were turned-in with the goats immediately following the $PGF_{2\alpha}$ injection and the goats were checked for breeding marks at 6-h intervals for 72 h.

2.3. Blood sampling and hormone assay

Blood samples were collected via jugular venipuncture from all goats once daily

starting immediately before CIDR-G insertion on day −12 until day 0 to verify progesterone concentrations during the period of progesterone priming among the groups. Blood samples were also collected once daily from day 0 until day 5 and every three days thereafter until day 23 to measure progesterone concentrations and determine pregnancy. Blood samples (5 mL each) were drawn into heparinized tubes (5 IU heparin·mL^{-1} blood) and centrifuged soon after collection. Plasma was pipetted and stored at −20 °C until it was assayed using radioimmunoassay (Progesterone Coat-A-Count Kit, Diagnostic Products Corporation, DPC, Los Angeles, CA). Sensitivity was 0.1 ng·mL^{-1} and the intra-assay coefficient of variation was 5.2%.

2.4. Statistical analysis

Data were analyzed using SAS/STAT ANOVA procedures (1996). Means ± SEM are presented in the text, tables and figures. The effects of progesterone (CIDR-G) priming prior to GnRH-PGF$_{2\alpha}$ treatment and eCG on the incidence of estrus, first-cycle pregnancy and kidding rates were analyzed by the categorical model (CATMOD) to determine the effects of CIDR-G and eCG treatments and their interactions. When significant effects were found, data were compared between treatment groups by the Chi-square test. The effects of the CIDR-G pretreatment and eCG at 0 h on various intervals were tested using the least-squares mean of the GLM procedures. Progesterone concentrations were analyzed for the effect of progesterone priming and time using the repeated-measures procedure of GLM. The ovulation or luteinization following GnRH treatment was considered to have occurred based upon progesterone levels of 0.4 ng·mL^{-1} or greater on day 0. The first-cycle pregnancy rate was defined as the number of goats bred by bucks within 72 h following day 0 and became pregnant based upon sustained progesterone levels of ≥ 3 ng·mL^{-1} between days 17 and 23 following day 0. Pregnancy

was confirmed on day 35 using a 5-MHz ultrasound transducer (485 Anser Vet, Pie Medical Equipment B.V., Philipsweg, AJ Maastricht, The Netherlands).

3. RESULTS

3.1. Progesterone concentrations from day −12 until day 0

No CIDR-G inserts were lost during the period of insertion. Plasma progesterone profiles among goats of the four groups from day −12 until day 0 are illustrated in Figure 1. Initial (day −12) progesterone concentrations were less than 0.3 ± 0.2 ng·mL^{-1} among the goats of four groups. During the period of progesterone priming, plasma concentrations increased rapidly and reached maximum values of 4.9 ± 0.5 and 4.8 ± 0.4 ng·mL^{-1} 2 days post CIDR-G insertion in CGPE and CGP groups, respectively, but remained below 0.3 ng·mL^{-1} in GPE and GP groups. Progesterone in CGPE and CGP groups decreased gradually by day ($P < 0.01$) during the remaining 3 days to 2.8 ± 0.1 and 2.6 ± 0.1 ng·mL^{-1}, respectively and were significantly different ($P < 0.001$) from those (0.3 ± 0.2 ng·mL^{-1}) of GPE and GP groups. Progesterone concentrations between days −10 and −7 were higher ($P < 0.001$) in CGPE and CGP than in GPE and GP groups, reflecting an exogenous treatment. On day −6, at the time of GnRH injection, which was given one day following CIDR-G removal, plasma concentrations were below 0.2 ± 0.04 ng·mL^{-1} and were similar among groups. The GnRH treatment was given when all goats had basal progesterone concentrations, which began to increase starting on day −2. On day 0, at the time of the PGF$_{2\alpha}$ injection, progesterone concentrations were elevated and averaged 1.8 ± 0.2, 1.2 ± 0.3, 0.7 ± 0.2 and 0.8 ± 0.2 ng·mL^{-1} for groups CGPE, CGP, GPE and GP, respectively. Progesterone concentrations on day 0 differed ($P < 0.05$) among groups and were significantly influenced by CIDR-G ($P < 0.001$) but not by
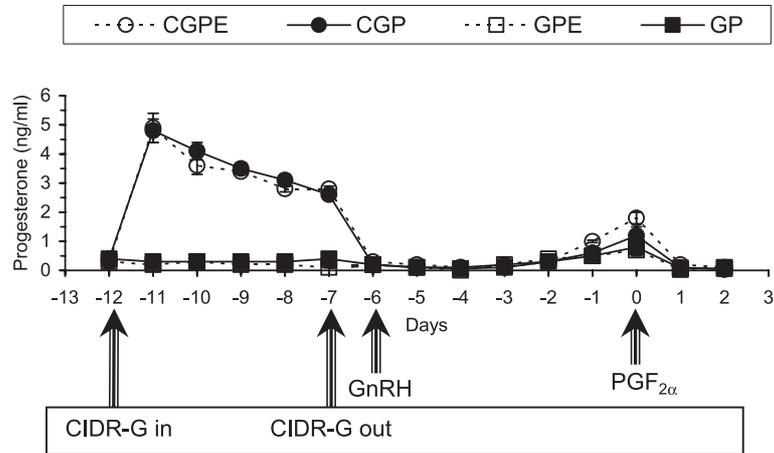

Figure 1. Plasma progesterone concentrations from day –12 until day 0 in GnRH-PGF$_{2\alpha}$-treated anestrous goats.

eCG or the interaction between CIDR-G and eCG (Fig. 1). The number of goats with elevated progesterone levels on day 0 was significantly greater ($P = 0.002$) in CGPE (9/9) and CGP (9/9) than GPE (6/9) and GP (5/9) groups and was significantly influenced by CIDR-G ($P = 0.03$) but not by eCG or the interaction between CIDR-G and eCG.

3.2. Reproductive performance following day 0

Reproductive performance following day 0 among the goats of the four groups is presented in Table I. Neither treatment (CIDR-G or eCG) nor their interaction had any effect ($P > 0.05$) on percentage of goats expressing estrus. Twenty-four hours before the PGF$_{2\alpha}$ injection, two goats, one from GPE and another from GP groups, showed homosexual activity and mucus vaginal discharge indicating estrus expression. Intervals from 0 h to detected estrus were significantly influenced by eCG ($P < 0.03$) but not by CIDR-G or the interaction between CIDR-G and eCG. Intervals were shorter ($P < 0.05$) in CGPE and GPE groups than in GP with no difference ($P > 0.1$)

between CGPE, CGP and GPE or between CGP and GP groups. However, more than 80% of the goats were bred between 18 and 42 h of buck introduction. The range of estrus occurrence was from 18–42, 24–54, 18–48 and 36–54 h for CGPE, CGP, GPE and GP, respectively.

Pregnancy was determined based upon progesterone concentrations on day 23 and confirmed on day 35 using ultrasonography. In pregnant goats, progesterone concentrations increased gradually after day 5 and remained elevated through day 23 (Fig. 2). In non-pregnant goats, progesterone concentrations increased after day 5 and then dropped after day 17. Pregnancy and kidding rates were influenced by CIDR-G ($P < 0.03$) but not by eCG or the interaction between CIDR-G and eCG. The proportion of goats that became pregnant and kidding was greater ($P < 0.05$) in CGPE than in GPE and GP with no differences between CGPE and CGP or between GPE and GP (Tab. I). The number of kids born per goat exposed was greater ($P < 0.05$) in CGPE than GPE and GP with no differences ($P > 0.1$) between CGPE and CGP or between CGP, GPE and GP groups. Using the GnRH-PGF$_{2\alpha}$ protocol, goats pretreated

with progesterone and having received 300 IU eCG injections concomitant with PGF$_{2\alpha}$ (CGPE) produced greater ($P < 0.05$) twinning percentages than the goats pre-treated with progesterone alone (CGP) or eCG alone (GPE) or neither (GP).

Data were retrospectively grouped, based upon progesterone concentrations on day 0, to compare parameters in goats with basal or elevated progesterone (ovulation or luteinization) levels on day 0. Progesterone concentrations were higher ($P < 0.01$) in goats that exhibited estrus (1.3 ± 0.1 vs. 0.5 ± 0.2 ng·mL^{-1}), became pregnant (1.4 ± 0.1 vs. 0.5 ± 0.2 ng·mL^{-1}), kidding (1.4 ± 0.1 vs. 0.6 ± 0.2 ng·mL^{-1}) and tended to be different ($P = 0.08$) in goats with multiple births (1.5 ± 0.2 vs. 1.1 ± 0.2 ng·mL^{-1}) than those that did not. Within group, progesterone concentrations in goats that became

pregnant and kidding were higher only in the GP group ($P < 0.005$) than goats that did not. All other parameters, within group, were found not to be different. Interestingly, all pregnant goats had elevated progesterone concentration on day 0 and none of the goats with basal progesterone levels became pregnant.

4. DISCUSSION

The results of the present study demonstrate that a 5-day progesterone priming prior to a GnRH-PGF$_{2\alpha}$ treatment combined with eCG at the time of PGF$_{2\alpha}$ injection was capable of producing higher rates of pregnancy and kidding. Such a treatment also caused a significant increase in the number of kids born, largely by increasing
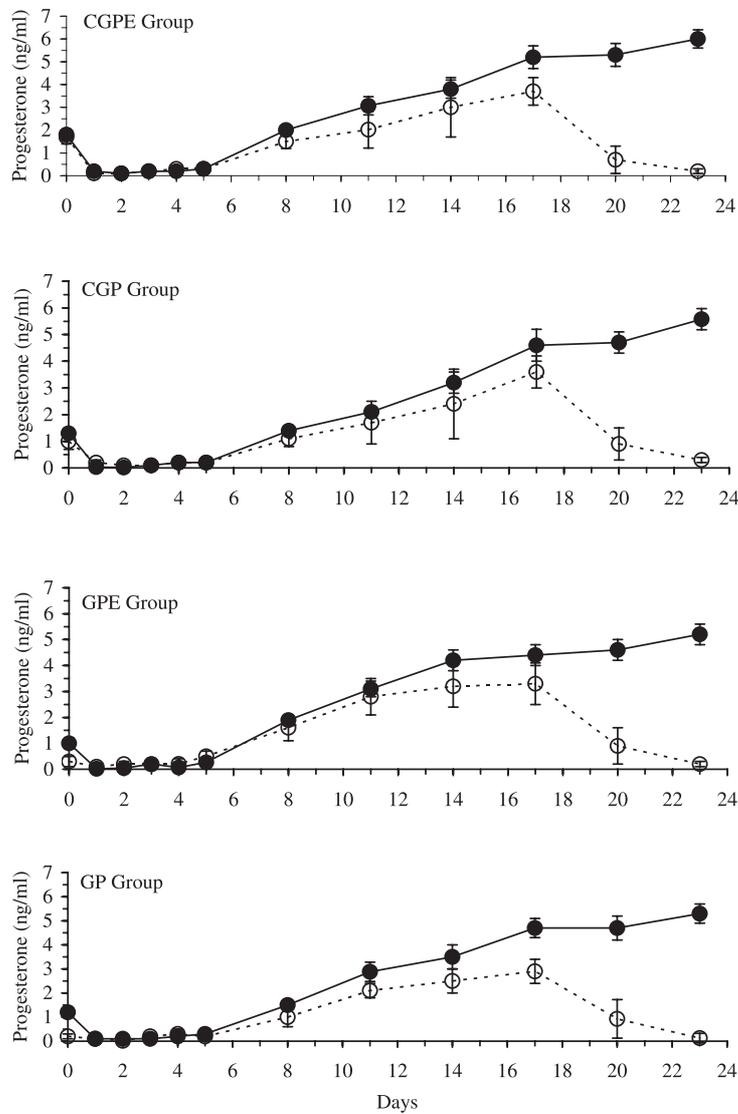

Figure 2. Plasma progesterone profiles following the $PGF_{2\alpha}$ injection in GnRH-$PGF_{2\alpha}$-treated anestrous goats. In pregnant ($\bullet$) ewes, progesterone concentrations increased and remained elevated through day 23. In non-pregnant ($\bigcirc$) ewes, progesterone concentrations increased and then dropped after day 17.

the number of twins in CGPE group. The data obtained from this study indicate that GnRH based protocols failed to induce fertile cycles in 55.6% (GPE and GP groups) of the goats, thus, progesterone pretreatment was essential for the efficiency of the GnRH-$PGF_{2\alpha}$ treatment in goats treated out-of-season. This assessment was qualified considerably by the excellent rates of estrus expression (100%), pregnancy

(100%) and kidding (88.9%) in the CGPE group. It is also noteworthy that there was a higher prolificacy rate among the goats of group CGPE compared to the three other groups. Such a successful outcome is primarily attributed to progesterone priming, illustrating its importance in out-of-season breeding programs.

It is generally accepted that progestagen-eCG treatment is necessary for out-of-season breeding in small ruminants. However, marginally acceptable fertility rates are usually accompanied such synchronization protocols [12]. Kidding rates between 52 and 66% have been reported out-of-season using CIDR-G and eCG [12]. During the breeding season, the use of CIDR-G has been reported to produce a kidding rate of 61% with [13] and 63% without eCG [14]. Results of CGPE group in the present study showed improvement in kidding rates (88.9%) compared with those mentioned above. Under Jordanian condition, prolificacy rate averages a little more than 1 kid/doe bred naturally and 1.5 kid/doe treated with progestagen-eCG. The CGPE protocol implemented in the present study has the potential to improve such low reproductive performance. Regarding cost, in Jordan, the CGPE protocol sell for about twice the price of progestagen-eCG. The additional expenses incurred in the present study can be justified by the benefits and return of kidding (88.9%) and prolificacy rate (2.1 kid/doe). This would bring a return of about 4–6 times the expenses spent for implementing such a protocol.

In the present study, the GnRH-PGF$_{2\alpha}$ protocol alone or with eCG produced low reproductive performance and failed to produce fertile cycles but was successful when goats were primed with progesterone. Progesterone priming prior to GnRH treatment has been shown to ensure normal luteal function in seasonally anestrous ewes [15, 16]. The abrupt rise in progesterone, following CIDR-G insertion, among goats of groups CGPE and CGP may have caused follicular atresia and emergence of a new follicular wave, which has been demonstrated in cattle [17]. Therefore, progesterone-pretreated goats are expected to have a medium to large size follicle and thus, would have been in mid to late stages of follicular growth at the time when GnRH was injected [18]. The effect of exogenous GnRH varies depending on the stage of the estrous cycle at which GnRH is administered [19, 20]. Presumably, the GnRH injection induces the preovulatory LH surge, which induces ovulation approximately 24–30 h following its administration [21] or atresia [22]. Moreover, it is expected that following the GnRH injection, the majority of goats will have similar reproductive patterns and thus, developing corpora lutea, perhaps sensitive enough to be influenced by the PGF$_{2\alpha}$ injection. Assuming that progesterone pretreatment mimicked normal luteal function in the CGPE and CGP groups, progesterone concentrations fell to basal values following CIDR-G removal and matched those of groups GPE and GP. Therefore, the GnRH injections were given when all goats had minimal progesterone concentrations. When the PGF$_{2\alpha}$ injection is given 6 days following GnRH, it regresses the newly formed corpus luteum from GnRH-induced ovulation, allowing the growth of a new follicular wave, with ovulation occurring 2–3 days later. These findings have been observed in dairy cows treated with GnRH-PGF$_{2\alpha}$ [8].

Based upon progesterone concentrations, the number of goats ovulating in response to GnRH injection was significantly increased in CIDR-G treated (CGPE and CGP) groups. As indicated by progesterone concentrations on day 0, all (100%) goats in CGPE and CGP groups had progesterone levels > 1.5 ng·mL^{-1} and all have responded to the PGF$_{2\alpha}$ injections. The increase in progesterone is related to the new corpora lutea formed following the GnRH-induced ovulation. The corpus luteum that forms after GnRH administration is capable of undergoing PGF$_{2\alpha}$-induced luteolysis following 5 days in goats [23] and sheep [24, 25]. Whereas, 33.3% and 44.4% of the

goats in groups GPE and GP, respectively, had basal progesterone levels on day 0 due to ovulation failure following the GnRH treatment and therefore, did not respond to the $PGF_{2\alpha}$ injection. Among goats with elevated progesterone levels on day 0, 8/9 CGPE, 7/9 CGP, 4/9 GPE and 4/9 GP goats became pregnant, reflecting the importance of elevated progesterone on this day. Progesterone priming had significantly elevated progesterone concentrations on day 0, which further improved the reproductive responses. Such a finding has previously been demonstrated in estrus-synchronized cattle [26]. Therefore, the increased number of goats with elevated progesterone concentrations on day 0, as observed in CGPE and CGP groups, was of significant value to the results of this study.

Among the groups, no differences were found in the percentages of goats expressing estrus. Progesterone pretreated goats and/or those that had eCG at the time of the $PGF_{2\alpha}$ injection exhibited estrus approximately 13 h earlier than non-progesterone goat that had not received eCG. Estrus distribution among groups occurred between 18 and 54 h following the $PGF_{2\alpha}$ injection, suggesting that the protocol adopted in this study is compact and effective in inducing estrus and producing higher rates of pregnancy and kidding. Although, progesterone priming for 5 days was efficient in inducing estrus in GnRH-$PGF_{2\alpha}$-treated anestrous goats, the influence of eCG should also be emphasized. Riter et al. [1] reported that eCG action on the ovaries stimulates follicular growth in cyclic or non-cyclic goats and enhances the rate of estrus expression. In agreement with the results of the present study, incorporation of eCG in estrus synchronization protocols reduces the interval from device removal to onset of estrus [27].

The seven goats that did not exhibit estrus within the 72 h following the $PGF_{2\alpha}$ injection were 2, 2 and 3 goats from CGP, GPE and GP groups, respectively. The absence of estrus may be due to inadequate estradiol secretion by the ovarian follicles, indicating incomplete follicular growth and development [28, 29]. For unknown reasons, one goat from GPE and another from GP expressed estrus 24 h before the $PGF_{2\alpha}$ injection. It maybe that GnRH treatment caused follicular atresia in those two goats and therefore, reset the follicular wave [7]. Emergence of a new follicular wave after GnRH injection may have led to development of a large follicle capable of producing sufficient estradiol that caused estrus signs [7, 30]. These two goats failed to ovulate in response to the GnRH injection given on day -6 and therefore, they are unlikely they respond to $PGF_{2\alpha}$. Such an incident has been observed in dairy cattle treated with GnRH-$PGF_{2\alpha}$ [31].

Results of the present study are in agreement with a previous study conducted under similar conditions in which GnRH-$PGF_{2\alpha}$-treated anestrous ewes were pretreated with progesterone for 4 days [11]. According to Billings and Katz [32], progesterone treatment for as little as 3 days facilitated estrogen-induced receptivity and attractivity of goats during the spring and fall. Corteel et al. [13] observed an improved conception rate in anestrous goats treated with CIDR-G and a combination of $PGF_{2\alpha}$ and eCG. Overall, the results indicate that the use of the GnRH-$PGF_{2\alpha}$ protocol without progesterone pretreatment in anestrus goats had no benefits in improving pregnancy and kidding rates or the number of kids born. In conclusion, the success of a GnRH-$PGF_{2\alpha}$-based program in anestrous goats is dependent on progesterone priming, which along with eCG are essential and offer the opportunity for producing higher rates of pregnancy and kidding. The actions of both progesterone and eCG reside, perhaps, in enhancing follicular growth and development.
