Analysis and Design of Equilibrium Points for the Cell-Transmission Traffic Model

Dominik Pisarski and Carlos Canudas-de-Wit

Abstract—The problem of equilibrium points for the Cell Transmission Model is studied. The structure of equilibrium sets is analyzed in terms of model parameters and boundary conditions. The goal is to determine constant input flows, so that the resultant steady state of vehicle density is uniformly distributed along a freeway. The necessary and sufficient conditions for the existence of one-to-one relation between input flow and density are derived. The equilibrium sets are described by formulas that allow to design a desired balanced density. A numerical example for the case of a two-cell system is presented.

I. INTRODUCTION

Mobility plays an important role in economy as well as in quality of human living. Every day the global impact of well organized transportation is counted in millions of tons fuel saved, thousands of fewer traffic accidents and thousands of kilograms carbon dioxide less emitted. These facts motivate even more intensive research on modeling and control of freeway systems. A good number of different control techniques, based on ramp metering and variable speed limiting, has been developed and put into practice. Most of these techniques enhance the exploitation of traffic systems by optimizing suitable metrics.

The most common metrics in use is the Total Travel Spent (TTS) and the Total Travel Distance (TTD). The former is to decrease the time of travel incurred by all drivers while the latter is to increase the usage of a freeway. TTS and TTD are often mixed with some extra terms, that penalize abrupt variations in ramp metering and speed limiting signals [1].

Most of the gradient optimization methods lead to open-loop solutions [2], [3], [4]. The Model Predictive Control procedure to coordinate both variable speed limits and ramp metering was presented in [5]. Optimization procedure based on the Powell's method was used to tune a close-loop regulator in [6]. A close-loop control system based on neural network was proposed in [7]. The sliding mode control method to prevent the propagation of shock waves was presented in [8]. The authors elaborated a decentralized scheme that exploits neighboring cellular information. ALINEA [9], one of the most common in use freeway regulators, optimizes the traffic flow by using a local control law. Some other optimization techniques for freeway systems can be found in [10], [11].

In this paper, we consider the problem of state balancing for freeway traffic system. The state of such a system is represented by distribution of vehicle density while on-ramp demands are assumed for the inputs. The objective is to find input flows that result in a uniform distribution of density. In practice, this uniform distribution can be understood as an equal interdistance between vehicles. The equal interdistance can be attractive to driver's point of view. It reduces the number and intensity of acceleration and deceleration events and therefore, it makes a travel more safety and comfortable, while decreasing emissions.

The problem of state balancing is also studied for other applications. For example, in the paper [12] the authors address the problem of averaging of a stored resource in batteries. They propose a distributed algorithm for flow control. The algorithm guarantees asymptotic convergence of states to the same value that is equal to the average of initial values.

In this paper, we investigate equilibrium sets for freeway system represented by the Cell Transmission Model (CTM). The goal for analysis is to explore balanced equilibria. The results will be crucial for future design of ramp metering strategy. A wide analysis of a behaviour of CTM was previously presented in [13]. The authors proved, that for CTM, every trajectory converges to some equilibrium state. They also showed, that for some cases, a unique input flow may produce an infinite set of equilibrium densities. The following questions then arise. What condition can assure the uniqueness of equilibrium states? What is the input that guarantees the balanced equilibrium state?

The contribution of this paper is the analysis of equilibrium sets for CTM in the context of design of balanced density equilibria. Both the qualitative and quantitative analysis is provided. In particular, the necessary and sufficient conditions for the existence of balanced equilibria are formulated. For the sake of steady state design, a relevant description of the equilibrium sets is given. Results are illustrated in a numerical example.

The organization of the paper is as follows. In the Section II, we give a brief description of CTM, together with its representation as a switched system. The preliminaries and definitions are introduced in the Section III. The Section IV is to analyse the structure of equilibrium sets. In the Section V we address the problem of design of balanced equilibrium density. Finally, conclusions are given.

Fig. 1. Freeway divided into n cells. Each cell is accompanied with one on-ramp and one off-ramp.

II. THE CELL TRANSMISSION MODEL AND STATE SPACE REPRESENTATION

In this paper, we consider a section of a freeway divided into cells as depicted in Fig. 1. Each cell is assumed to be equipped with one on-ramp and one off-ramp. For such a system, we adopt Daganzo's Cell Transmission Model (CTM), introduced in [14].

For the cell i we assume the following notation: ρ_i —vehicle density, ϕ_i —mainstream flow entering the cell, r_i —on-ramp flow entering the cell, s_i —off-ramp flow leaving the cell, v_i —free flow speed, w_i —congestion wave speed, F_i —capacity, $\bar{\rho}_i$ —jam density, l_i —cell length. The relation between flow and density is represented by the triangular fundamental diagram (see Fig. 2).

CTM describes the evolution of the system in discrete time $t_k = k \Delta t$, with $k \in \mathbb{N}$. Time step $\Delta t > 0$ is taken small enough to provide convergence condition (for details see [15]). For the cell i the governing equation is:

$$\rho_i(k+1) = \rho_i(k) + \frac{\Delta t}{l_i} [\Phi_i^+(k) - \Phi_i^-(k)]. \quad (1)$$

Here $\Phi_i^+(k)$ and $\Phi_i^-(k)$ are total flows entering and leaving the cell i , i.e.:

$$\begin{aligned} \Phi_i^+(k) &= \phi_i(k) + r_i(k), \\ \Phi_i^-(k) &= \phi_{i+1}(k) + s_i(k). \end{aligned} \quad (2)$$

By introducing Demand D_i and Supply S_i functions:

$$\begin{aligned} D_i(k) &= \min \{ \bar{\beta}_i v_i \rho_i(k), F_i \}, \\ S_i(k) &= \min \{ w_i (\bar{\rho}_i - \rho_i(k)), F_i \} \end{aligned} \quad (3)$$

according to Daganzo's merge connection model mainstream and on-ramp flows for $i = 0, 1, \dots, n-1$ are given as follows:

if $D_{i-1}(k) + u_i(k) \leq S_i(k)$:

$$\phi_i(k) = D_{i-1}(k), \quad r_i(k) = u_i(k)$$

otherwise :

$$\begin{aligned} \phi_i(k) &= \text{mid} \{ D_{i-1}(k), S_i(k) - u_i(k), (1 - p_i) S_i(k) \}, \\ r_i(k) &= \text{mid} \{ u_i(k), S_i(k) - D_{i-1}(k), p_i S_i(k) \}. \end{aligned} \quad (4)$$

Here the function $\text{mid} \{ \cdot \}$ returns the middle value. We will say, that the cell i is in free state if $\rho_i v_i \leq F_i$. Otherwise, it is in congested state.

In (4) we introduced on-ramp demands u_i that will appear later as the inputs for the control system. By $p_i \in [0, 1]$ we denote a parameter, that captures the priorities between mainstream flow ϕ_i and on-ramp flow r_i when merging in a cell during the congestion. In order to determine the value

Fig. 2. The fundamental diagram. The shape is determined by the parameters: F - capacity, v - free flow velocity, w - congestion wave speed.

for p_i we should consider geometrical properties of on-ramp as well as drivers' behaviour. For the most of the cases, we can assume, that the priority is for the mainstream flow, and therefore we set $p_i < 0.5$.

The boundary conditions are determined by some demand function $\bar{D}(k) = D_{-1}(k)$ for the cell 0 and some supply function $\bar{S}(k) = S_n(k)$ for the cell $n - 1$. For the flow ϕ_n we adopt the simple connection model, and therefore:

$$\phi_n(k) = \min \{ D_{n-1}(k), \bar{S}(k) \}. \quad (5)$$

Finally, for the off-ramp flows we assume:

$$s_i(k) = \frac{1 - \bar{\beta}_i}{\beta_i} \phi_{i+1}(k). \quad (6)$$

Here $\bar{\beta}_i = 1 - \beta_i$, where $\beta_i \in [0, 1]$ stands for the split ratio, which is the parameter, that specifies a number of vehicles leaving the cell i .

For the convenience of our further investigation, we rewrite the governing equation (1) in a form of a switched control system:

$$\begin{aligned} x(k+1) &= A_{s(k)} x(k) + B_{s(k)} u(k) + C_{s(k)}(k), \\ s(k) &= f(x(k), u(k)). \end{aligned} \quad (7)$$

Here the state vector $x \in \mathcal{X}$ and the input vector $u \in \mathcal{U}$ stand for vehicle densities and input flows (on-ramp demands), respectively:

$$x = (\rho_0, \rho_1, \dots, \rho_{n-1}), \quad u = (u_0, u_1, \dots, u_{n-1}). \quad (8)$$

The sets $\mathcal{X} \in \mathcal{R}^n$ and $\mathcal{U} \in \mathcal{R}^n$ respect minimum and maximum values for densities and on-ramp demands. The switching variable $s \in \mathcal{S} = \{1, 2, \dots, m\}$ indicates a mode of the system, and it determines terms in the matrices $A^{n \times n}$, $B^{n \times n}$ and for the vector $C^{n \times 1}(k)$. The vector $C^{n \times 1}(k)$ consist of the boundary functions $\bar{D}(k)$ and $\bar{S}(k)$. Notice that m is a total number of all possible modes generated by nonlinear formulas for mainstream and on-ramp flows.

III. PROBLEM FORMULATION

As it was stated in the introduction, the goal of this paper is to analyse the structure of equilibrium sets for CTM. In particular, we will investigate sets of balanced equilibrium points. Before going into the analysis, we first introduce some formal definitions.

Definition The equilibrium set Δ for CTM described by (7) is a set of pairs (x^*, u^*) that under a fixed boundary conditions solve the following equilibrium equation:

$$\begin{aligned} (A_s - \mathbf{I})x^* + B_s u^* + C_s &= 0, \\ s &= f(x^*, u^*), \quad s \in \mathcal{S}. \end{aligned} \quad (9)$$

Here \mathbf{I} stands for the identity matrix. In terms of (1) the steady state is reached when for every cell, the total flow entering and leaving are equal. Notice that vectors C_s becomes constant, when boundary conditions have fixed value, i.e.: $\bar{D}(k) = \bar{D}$ and $\bar{S}(k) = \bar{S}$. By Δ_x and Δ_u we denote the set of equilibrium density and equilibrium input flow, respectively.

In order to analyse the structures of Δ we need to represent it in a more convenient way. This can be done by introducing a relevant set of inequalities. First, we decompose Δ into subsets that correspond to the modes of the system. For every $s \in \mathcal{S}$ we define the following set:

$$\Delta_s = \{(x^*, u^*) : (A_s - \mathbf{I})x^* + B_s u^* + C_s = 0, \quad s = f(x^*, u^*)\}. \quad (10)$$

Then we have $\Delta = \bigcup_{s=1}^m \Delta_s$. The function f results from $\text{mid}\{\cdot\}$ and $\text{min}\{\cdot\}$ terms in (3)–(5). Therefore, by introducing relevant inequalities we can rewrite every Δ_s as:

$$\Delta_s = \{(x^*, u^*) : (A_s - \mathbf{I})x^* + B_s u^* + C_s = 0, \quad K_s x^* + L_s u^* + M_s \leq 0\}. \quad (11)$$

Here the matrices K_s , L_s and the vector M_s are constant. To illustrate how to build inequalities in (11) we give an example for the case of a two-cell system. Using (1)–(6) we can write:

$$\begin{aligned} \text{for } s = 1 : \quad & \bar{D} + u_0^* = \frac{1}{\beta_0} D_0, \quad D_0 + u_1^* = \frac{1}{\beta_1} D_1, \\ & \bar{D} + u_0^* \leq S_0, \quad D_0 + u_1^* \leq S_1, \quad D_1 \leq \bar{S}, \\ \text{for } s = 2 : \quad & S_0 = \frac{1}{\beta_0} D_0, \quad D_0 + u_1^* = \frac{1}{\beta_1} D_1, \\ & \bar{D} + u_0^* \geq S_0, \quad D_0 + u_1^* \leq S_1, \quad D_1 \leq \bar{S}, \\ \text{and so forth, till } s &= m. \end{aligned} \quad (12)$$

Inserting relevant formulas for Demand and Supply functions for $s = 1$ we have:

$$\begin{aligned} \begin{bmatrix} -v_0 & 0 \\ \bar{\beta}_0 v_0 & -v_1 \end{bmatrix} \begin{bmatrix} x_0^* \\ x_1^* \end{bmatrix} + \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} u_0^* \\ u_1^* \end{bmatrix} + \begin{bmatrix} \bar{D} \\ 0 \end{bmatrix} &= 0, \\ \begin{bmatrix} w_0 & 0 \\ \bar{\beta}_0 v_0 & w_1 \\ 0 & \bar{\beta}_1 v_1 \end{bmatrix} \begin{bmatrix} x_0^* \\ x_1^* \end{bmatrix} + \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} u_0^* \\ u_1^* \end{bmatrix} + \begin{bmatrix} \bar{D} - w_0 \bar{\rho}_0 \\ -w_1 \bar{\rho}_1 \\ -\bar{S} \end{bmatrix} &\leq 0. \end{aligned} \quad (13)$$

For the set Δ we will pay the special attention to these points (x^*, u^*) , where x^* are balanced. Before we describe this balance, let us introduce a set of admissible balanced density:

$$\mathcal{C} = \{c : 0 \leq c \leq \min\{\bar{\rho}_i\}_{i=0}^{n-1}\}. \quad (14)$$

Then the set of balanced equilibrium points $\Delta_B \subset \Delta$ is defined as follows:

Definition Δ_B is a set of equilibrium points (x^*, u^*) , such that the equilibrium density is balanced, i.e.:

$$x^* = c \mathbf{1}, \quad c \in \mathcal{C}. \quad (15)$$

Here $\mathbf{1}^{n \times 1}$ stands for all-ones vector. By analogy to the set Δ we will denote by Δ_{xB} and Δ_{uB} the set of balanced equilibrium densities and the set of related equilibrium input flows, respectively.

The objectives of this paper are as follows. To determine how the shape of Δ corresponds to model parameters. To derive a condition, that ensures the existence of the set Δ_B . To provide formulas, that enable us to find input flows u^* , so that the resulting equilibrium density x^* is balanced.

Before we go further, we need to recall some basic facts on the relation between the sets Δ_u and Δ_x . In the paper [13], it was presented, that in general the mapping $\Delta_u \rightarrow \Delta_x$ is not one-to-one. The authors provided a simple example, where they fixed values for demands and input flows. The resulting equilibrium density was not a unique point. It was represented by some set of points instead. It was shown, that the steady state was determined not only by the input but also by the initial state. Therefore, for such a case, the design of density equilibria is not feasible. In this paper, we consider only these cases for which any fixed input flow results in a unique equilibrium density. Moreover, we focus only on these points of $(x^*, u^*) \in \Delta$ such that the mapping $\Delta_u \rightarrow \Delta_x$ is bijective. Notice that $\Delta_u \rightarrow \Delta_x$ is bijective for the mode s iff both $(A_s - \mathbf{I})$ and B_s are invertible.

IV. STRUCTURE OF EQUILIBRIUM SETS

In this section, we describe the structure of the set Δ . As stated before, we limit our investigation to these equilibria that respect the one-to-one property. From (4) we can observe that matrix B_s is invertible iff the following conditions are satisfied:

$$\begin{aligned} \bar{D} + u_0^* &\leq S_0, \\ D_{i-1} + u_i^* &\leq S_i, \quad i = 1, 2, \dots, n-1. \end{aligned} \quad (16)$$

Under this assumption, the equilibrium equation in (9) is represented by:

$$\begin{aligned} \bar{D} + u_0^* &= \frac{1}{\beta_0} D_0, \\ D_{i-1} + u_i^* &= \frac{1}{\beta_i} D_i, \quad i = 1, 2, \dots, n-2, \\ D_{n-2} + u_{n-1}^* &= \frac{1}{\beta_{n-1}} \min\{D_{n-1}, \bar{S}\} \end{aligned} \quad (17)$$

To ensure the invertibility of $(A_s - \mathbf{I})$ we need to impose additional conditions, i.e.:

$$D_{n-1} \leq \bar{S}, \quad \bar{\beta}_i v_i x_i^* \leq F_i, \quad i = 0, 1, \dots, n-1. \quad (18)$$

Under the condition (18) we can rewrite (17) as follows:

$$\begin{aligned} \bar{D} + u_0^* &= v_0 x_0^*, \\ \bar{\beta}_{i-1} v_{i-1} x_{i-1}^* + u_i^* &= v_i x_i^*, \quad i = 1, 2, \dots, n-1. \end{aligned} \quad (19)$$

Let us define Γ as the one-to-one mapping $\Delta_u \rightarrow \Delta_x$ described by (19).

Based on (16)–(18) we can formulate the necessary condition for the existence of Γ in terms of boundary and input flows.

Proposition 4.1: There exist the mapping Γ only if:

$$\prod_{i=0}^{n-1} \bar{\beta}_i \bar{D} + \sum_{i=0}^{n-1} \left(\prod_{j=i}^{n-1} \bar{\beta}_j u_i^* \right) \leq \bar{S} \quad (20)$$

Proof: From (18) we have:

$$D_{n-1} \leq \bar{S}. \quad (21)$$

Inserting D_{n-1} from (17) we obtain:

$$\bar{\beta}_{n-1} D_{n-2} + \bar{\beta}_{n-1} u_{n-1}^* \leq \bar{S}. \quad (22)$$

Repeating this substitution from D_{n-2} to D_0 we get (20). ■

For the analysis of the equilibrium set we consider only two special cases. In the first case we assume, that all cells are in the free state. Then we describe the shape of Δ in terms of system parameters. The second case is to show, that for the congested state, the conditions (16)–(18) drive to contradiction.

A. Set of free equilibrium points

Definition The set of *free equilibrium points* $\Delta^f \subset \Delta$ is a set of pairs (x^*, u^*) where x^* is the free state, i.e.:

$$v_i x_i^* \leq F_i, \quad i = 0, 1, \dots, n-1. \quad (23)$$

Consistently, we will denote by Δ_x^f and Δ_u^f the sets of free equilibrium densities and sets of corresponding equilibrium input flows, respectively

Now we will formulate the sufficient condition for the existence of Γ under $x^* \in \Delta_x^f$. First we show, that the condition:

$$\bar{\beta}_i v_i x_i^* \leq F_i, \quad i = 0, 1, \dots, n-1. \quad (24)$$

Fig. 3. An example of the set of free equilibrium densities for the case of two-cell system. The grey trapezium is for the set Δ_x^f . The blue line indicates balanced states.

Fig. 4. An example of the set of free equilibrium input flows for the case of two-cell system. The grey triangle is for the set Δ_u^f .

is satisfied. Indeed, it is because for $\bar{\beta}_i \leq 1$ we have:

$$\bar{\beta}_i v_i x_i^* \leq v_i x_i^* \leq F_i, \quad i = 0, 1, \dots, n-1. \quad (25)$$

Proposition 4.2: Let x^* be some free state equilibrium. Then, there exist the mapping Γ if the following conditions hold:

$$\begin{aligned} \bar{D} + u_0^* &\leq F_0, \\ \bar{\beta}_{i-1} v_{i-1} x_{i-1}^* + u_i^* &\leq F_i, \quad i = 1, 2, \dots, n-1, \\ \bar{\beta}_{n-1} v_{n-1} x_{n-1}^* &\leq \bar{S}. \end{aligned} \quad (26)$$

Finally, we can describe the sets Δ_x^f and Δ_u^f as follows:

$$\begin{aligned} \Delta_x^f &= \{x^* \in \mathcal{X} : \\ &v_i x_i^* \leq F_i, \quad i = 0, 1, \dots, n-1, \\ &x_0^* = \frac{\bar{D} + u_0^*}{v_0}, \\ &x_i^* = \frac{\bar{\beta}_{i-1} v_{i-1} x_{i-1}^* + u_i^*}{v_i}, \quad i = 1, 2, \dots, n-1, \\ &u^* \in \Delta_u^f \}, \end{aligned} \quad (27)$$

$$\begin{aligned} \Delta_u^f &= \{u^* \in \mathcal{U} : \\ &u_0^* \leq F_0 - \bar{D}, \\ &u_1^* \leq F_1 - \bar{\beta}_0 (\bar{D} + u_0^*), \\ &u_2^* \leq F_2 - \bar{\beta}_1 (\bar{\beta}_0 (\bar{D} + u_0^*) + u_1^*) \\ &\text{and so forth} \}. \end{aligned} \quad (28)$$

In Fig. 3 we present the shape of Δ_x^f (grey trapezium) for the case of a two-cell system. The corresponding set Δ_u^f is represented by grey triangle depicted in Fig. 4. We can observe how the system parameters affect on Δ_x^f . For instance, if the slope of the left bound (indicated by red line) is less than 1, then the set is represented by a triangle placed below the blue line indicating balanced states. Therefore, in this case the set Δ_{xB} would be empty. We will explore this fact in details in the section V.

B. Set of congested equilibrium points

Definition The set of *congested equilibrium points* $\Delta^c \subset \Delta$ is a set of pairs (x^*, u^*) where x^* is the congested state, i.e.:

$$v_i x_i^* > F_i, \quad i = 0, 1, \dots, n-1. \quad (29)$$

Now we will show, that under the conditions (16)–(18) the set Δ^c is empty. For the congested case ($S_i < F_i$ for all i) the condition in (16) is as follows:

$$\bar{D} + u_0 \leq S_0 < F_0. \quad (30)$$

On the other we have assumed that:

$$x_0^* v_0 > F_0. \quad (31)$$

Thus the equality:

$$\bar{D} + u_0 = x_0^* v_0 \quad (32)$$

is a contradiction and therefore, for the congested case the mapping Γ does not exist.

V. DESIGN OF BALANCED EQUILIBRIUM STATES

So far, we have derived the necessary and sufficient conditions for the existence of Γ – the relation, that allows us to design equilibrium densities $x^* \in \Delta_x$. In order to design balanced equilibrium $x^* \in \Delta_{xB}$, we need to impose some additional requirements.

In the previous section, we proved that Γ exists only for the free state case. Therefore, for the admissible balanced densities we consider only these points $c \in \mathcal{C}$ that satisfy the condition:

$$c \leq \min \left\{ \frac{F_i}{v_i} \right\}_{i=0}^{n-1}. \quad (33)$$

Then the set of balanced equilibrium points Δ_B can be defined as a set of pairs (u^*, c) , that solve the equations:

$$\begin{aligned} \bar{D} + u_0^* &= v_0 c, \\ \bar{\beta}_{i-1} v_{i-1} c + u_i^* &= v_i c, \quad i = 1, 2, \dots, n-1. \end{aligned} \quad (34)$$

Respecting real freeway scenarios we have to assume:

$$u^* \geq 0. \quad (35)$$

Then we can formulate the necessary condition for the existence of balanced equilibria.

Proposition 5.1: Let $u_i^* \geq 0$ for $i = 0, 1, \dots, n-1$. Then, there exists a balanced free equilibrium point only if:

$$\bar{\beta}_{i-1} v_{i-1} \leq v_i, \quad i = 1, 2, \dots, n-1. \quad (36)$$

Proof: Let us assume $\bar{\beta}_{i-1} v_{i-1} > v_i$ for $i = 1, 2, \dots, n-1$. Then (34) is a contradiction under $u \geq 0$. ■

Remark A practical fact comes up with the Proposition 5.1. In order to design a balanced equilibrium point we may need to apply the variable speed limiting, where the speed limits depend on actual values of the split ratios.

Finally, we can describe the sets of balanced equilibrium points:

$$\begin{aligned} \Delta_{xB}^f &= \{x^* = c\mathbf{1} : \\ c &\leq \min \left\{ \frac{F_i}{v_i} \right\}_{i=0}^{n-1}, \quad c = \frac{\bar{D} + u_0^*}{v_0}, \\ u^* &\in \Delta_{uB}^f \}, \end{aligned} \quad (37)$$

Fig. 5. Numerical example for the set Δ_{xB}^f (color line). The left end of the line corresponds to the input flow vector: $u_0^* = 0, u_1^* = 0$ while the right one is for $u_0^* = 1000, u_1^* = 0$.

$$\Delta_{uB}^f = \{u^* \in \mathcal{U} : \}$$

$$\begin{aligned} u_0^* &\leq v_0 \min \left\{ \frac{F_i}{v_i} \right\}_{i=0}^{n-1} - \bar{D}, \\ u_i^* &\leq (v_i - \bar{\beta}_{i-1} v_{i-1}) \min \left\{ \frac{F_i}{v_i} \right\}_{i=0}^{n-1}, \\ \frac{\bar{D} + u_0^*}{v_0} &= \frac{u_i^*}{v_i - \bar{\beta}_{i-1} v_{i-1}}, \quad i = 1, 2, \dots, n-1 \}, \end{aligned} \quad (38)$$

A. Optimal balanced equilibrium point

Among the points $x^* \in \Delta_{xB}^f$ we can find the one that optimizes some objective function. For example, we can consider the balanced equilibrium state that maximizes the total input volume (TIV). We define TIV as follows:

$$J_{TIV} = \sum_{i=0}^{n-1} u_i^*. \quad (39)$$

Then the optimal balanced equilibrium density is:

$$x^{**} = \frac{\bar{D} + u_0^{**}}{v_0} \mathbf{1}, \quad (40)$$

where u_0^{**} solves the following optimization problem:

$$\begin{aligned} \text{Find } u_0^{**} &= \max u_0^*, \\ \text{under } u^* &\in \mathcal{U}, \\ u_0^* &\leq v_0 \min \left\{ \frac{F_i}{v_i} \right\}_{i=0}^{n-1} - \bar{D}, \\ u_i^* &\leq (v_i - \bar{\beta}_{i-1} v_{i-1}) \min \left\{ \frac{F_i}{v_i} \right\}_{i=0}^{n-1}, \\ \frac{\bar{D} + u_0^*}{v_0} (v_i - \bar{\beta}_{i-1} v_{i-1}) &\leq u_i^*, \\ i &= 1, 2, \dots, n-1. \end{aligned} \quad (41)$$

B. Numerical example

To illustrate the results, we present the numerical example for a two-cell system. We assume that all cells have the same free flow speeds and there is no off-ramps ($\bar{\beta}_0 = \bar{\beta}_1 = 1$). In this case, from (34) we immediately conclude, that a

Fig. 6. State orbits (color curves) and balanced equilibrium density (green dot) for the case of $u_0^* = 500$, $u_1^* = 0$.

balanced equilibrium exists only if the downstream input flow is equal to zero, i.e. $u_1^* = 0$ and only the first on-ramp serves the vehicles $u_0^* \geq 0$. The parameters are assumed as follows: $v_0 = v_1 = 60$ (km/h), $w_0 = w_1 = 20$ (km/h), $F_0 = F_1 = 6000$ (veh/h), $\bar{\rho}_0 = \bar{\rho}_1 = 400$ (veh/km), $\bar{D} = 5000$ (veh/h). Then the following is the admissible input flow vector: $u_0^* \in [0, 1000]$ (veh/h) and $u_1^* = 0$. The corresponding set Δ_{xB}^f is plotted in Fig 5 as color line. Colors correspond to the values of u_0^* as indicated on the bar.

In Fig. 6 we present the state trajectories for the case of $u_0^* = 500$ (veh/h) and $u_1^* = 0$. The attractive point is $x_0^* = x_1^* = 91.6$ (veh/km).

VI. CONCLUSIONS AND FUTURE WORKS

In this paper, the analysis of structure of equilibrium sets for the Cell Transmission Traffic Model has been presented. We have limited our attention to the case, that provides one-to-one mapping between inputs and equilibrium states. This case requires two conditions to be satisfied. First, total demand weighted with split ratios must not exceed supply for the downstream boundary. Second, all cells are in the free state. Under these conditions, we have shown, that the balanced state exists only if the additional relation between free flow velocities and split ratios holds. This suggests that in practical design of balanced equilibria, we may need to use both ramp metering and variable speed limiting, where speed limits depend on actual values of split ratios. For the special case, where parameters for all cells are equal and there is no off-ramps, the balanced state is possible only if the first on-ramp is serving cars while others are closed. In future works, we will address the problem of state balancing for the cases, where the necessary conditions presented here are not fulfilled. The idea is to approach near balanced state while staying within the equilibrium set. This will be formulated as an optimization problem. Further step will be to find near

balanced state, so that some objective (for example, TTD) is optimized.
