**Abstract** — We show that the use of a round function whose Walsh coefficients are divisible by a high power of 2 may lead to a higher order differential attack.

## I. HIGHER ORDER DIFFERENTIAL ATTACKS

We consider an  $r$ -round iterated block cipher with block size  $n$ :  $F_{k_r} \circ F_{k_{r-1}} \circ \dots \circ F_{k_1}$  where the round function  $F_k$  is a permutation of  $\mathbf{F}_2^n$  for any  $k$ . Such a cipher is vulnerable to linear cryptanalysis if there exists  $(\alpha, \beta)$ ,  $\alpha \neq 0$  such that  $\alpha \cdot F_k(x) + \beta \cdot x$  takes the same value for most values of  $x \in \mathbf{F}_2^n$ . This property is related to the Walsh spectrum of  $F_k$ .

For any  $\alpha \in \mathbf{F}_2^n$ ,  $\varphi_\alpha$  denotes the linear function  $x \mapsto \alpha \cdot x$  where “ $\cdot$ ” is the usual dot product. The Walsh spectrum of a function  $F$  from  $\mathbf{F}_2^n$  into  $\mathbf{F}_2^n$  is the multiset

$$\{\mathcal{F}(\varphi_\alpha \circ F + \varphi_\beta) = \sum_{x \in \mathbf{F}_2^n} (-1)^{\alpha \cdot F(x) + \beta \cdot x}, \alpha \in \mathbf{F}_2^n \setminus \{0\}, \beta \in \mathbf{F}_2^n\}.$$

The nonlinearity of  $F$  is the Hamming distance between all  $\varphi_\alpha \circ F$  and the set of affine functions. It is equal to

$$2^{n-1} - \frac{1}{2} \mathcal{L}(F) \quad \text{where} \quad \mathcal{L}(F) = \max_{\alpha \in \mathbf{F}_2^n} \max_{\beta \in \mathbf{F}_2^n} |\mathcal{F}(\varphi_\alpha \circ F + \varphi_\beta)|.$$

The minimum value for  $\mathcal{L}(F)$  is  $2^{\frac{n+1}{2}}$  and the functions achieving this value are called *almost bent functions*. They provide a high resistance to both linear and differential attacks [2].

The derivative of a function  $F$  over  $\mathbf{F}_2^n$  with respect to a linear subspace  $V$  is defined by  $D_V F(x) = \sum_{v \in V} F(x+v)$  where the sum is an addition modulo 2. Suppose that for any round keys, the reduced cipher, i.e., the function  $G = F_{k_{r-1}} \circ \dots \circ F_{k_1}$ , has degree  $d$  (the degree of  $G$  is the maximum degree of its Boolean components). Then, for any  $(d+1)$ -dimensional subspace  $V$ , we have  $\sum_{v \in V} G(x+v) = 0$  for all  $x \in \mathbf{F}_2^n$ . It leads to a differential attack of order  $(d+1)$  [4]:

1. Select a random plaintext  $x_0 \in \mathbf{F}_2^n$  and get the ciphertexts  $c_v$  corresponding to all plaintexts  $x_0 + v$ ,  $v \in V$ .
2. For each candidate for  $k_r$ , compute  $\sum_{x \in V} F_{k_r}^{-1}(c_v)$ .

The key  $k_r$  for which this sum vanishes is the correct last-round key with a high probability. But, the bound  $\deg(G) \leq (\deg(F))^{r-1}$  only enables to apply the attack to the ciphers with low degree round functions.

## II. DIVISIBILITY OF THE WALSH SPECTRUM AND DEGREE OF A COMPOSED FUNCTION

The trivial bound  $\deg(F \circ F) \leq \deg(F)^2$  can be improved when the values occurring in the Walsh spectrum of  $F$  are divisible by a high power of 2. By using a relation between the Walsh coefficients of the sum of some Boolean functions and the Walsh coefficients of their product, we can prove

**Theorem 1** Let  $F$  be a function from  $\mathbf{F}_2^n$  into  $\mathbf{F}_2^n$  such that all values occurring in its Walsh spectrum are divisible by  $2^\ell$ . Then, for any function  $F'$  from  $\mathbf{F}_2^n$  into  $\mathbf{F}_2^n$ , we have

$$\deg(F' \circ F) \leq n - \ell + \deg(F').$$

This result is of great interest when  $F$  is almost bent since the Walsh coefficients of any almost bent function over  $\mathbf{F}_2^n$  are divisible by  $2^{\frac{n+1}{2}}$  [2]. It leads to a new attack on any 5-round Feistel cipher using a highly nonlinear substitution function. In a Feistel cipher with block size  $2n$ , the round function is defined by  $(L, R) \mapsto (R, L + S_k(R))$  where  $L$  and  $R$  are the left and right halves of the input and  $S_k$  is a function over  $\mathbf{F}_2^n$  called the substitution function. The right part of the output of the third round,  $R_3$ , can be derived from the ciphertext  $(L_5, R_5)$  and from  $k_5$ :  $R_3 = R_5 + S_{k_5}(L_5)$ . Moreover, when we consider any plaintext  $(x, c_0)$  whose right part is a constant, we have  $R_3(x) = x + c_1 + S_{K_3}(c_0 + S_{K_2}(x + c_1))$ . When the confusion function  $S$  is almost bent, Theorem 1 implies that  $\deg(R_3) \leq \frac{n-1}{2} + \deg(S)$ . Thus, we have exhibited a new differential attack of order  $\delta = \min((\deg(S)^2 + 1, \frac{n+1}{2} + \deg(S))$ . Since the degree of an almost bent function cannot exceed  $(n+1)/2$ , this attack is feasible except for almost bent functions of maximal degree. But, it can be improved and performed for any almost bent functions when the round key is inserted by addition. It also applies when  $S_k$  is a permutation of an even number of variables which has the highest known nonlinearity. Except the inverse function, all known permutations  $S$  achieving  $\mathcal{L}(S) = 2^{n/2+1}$  are such that all their Walsh coefficients are divisible by either  $2^{n/2}$  or  $2^{n/2+1}$  [3].

Theorem 1 also provides an explanation and a generalization of a 7-order differential attack on a reduced version of MISTY1 [6, 1]. This weakness originates from the use of almost bent substitution boxes in the cipher.
