NodeTrix: A Hybrid Visualization of Social Networks

Nathalie Henry, Jean-Daniel Fekete, and Michael J. McGuffin

Abstract— The need to visualize large social networks is growing as hardware capabilities make analyzing large networks feasible and many new data sets become available. Unfortunately, the visualizations in existing systems do not satisfactorily resolve the basic dilemma of being readable both for the global structure of the network and also for detailed analysis of local communities. To address this problem, we present NodeTrix, a hybrid representation for networks that combines the advantages of two traditional representations: node-link diagrams are used to show the global structure of a network, while arbitrary portions of the network can be shown as adjacency matrices to better support the analysis of communities. A key contribution is a set of interaction techniques. These allow analysts to create a NodeTrix visualization by dragging selections to and from node-link and matrix forms, and to flexibly manipulate the NodeTrix representation to explore the dataset and create meaningful summary visualizations of their findings. Finally, we present a case study applying NodeTrix to the analysis of the InfoVis 2004 coauthorship dataset to illustrate the capabilities of NodeTrix as both an exploration tool and an effective means of communicating results.

Index Terms—Network visualization, Matrix visualization, Hybrid visualization, Aggregation, Interaction.

1 Introduction

Social network analysis is a growing area of the social sciences. Vast new datasets are becoming available as people conduct ever more of their social lives electronically. Online projects such as Wikipedia or open-source software development are creating new social networks on a global scale. At the same time, the challenges of a more integrated world generate new demands for analysis such as monitoring terrorist networks or the spread of potentially pandemic diseases. Social network visualization is becoming a popular topic in information visualization, generating more and more tools for analysts. In 2006, 10 network-related articles (or 30%) were presented at the InfoVis Symposium and 6 at the VAST symposium. The large majority of network visualization systems use the node-link representation: 54 (out of 55) node-link based systems are referenced in the Social Network Analysis Repository (`http://www.insna.org/`), and 49 (out of 52) on the Visual Complexity website (`http://www.visualcomplexity.com/`). This representation is well suited to show sparse networks, but social networks are known to be globally sparse and locally dense. Therefore, social network visualization faces a major challenge: obtaining a readable representation for both the overall sparse structure of a social network and its dense communities.

In this article, we propose a novel visualization called *NodeTrix* to address this challenge. NodeTrix integrates the best of the two traditional network representations by using node-link diagrams to visualize the overall structure of the network, within which adjacency matrices show communities.

The article is organized as follows: after the related work section, we describe the NodeTrix representation and the data structure we rely on. We then detail the interaction techniques we designed for creating a NodeTrix hybrid, either by starting from a standard node-link diagram or from a standard adjacency matrix. Finally, we describe a case study using NodeTrix to explore and present the results of a coauthorship social network.

2 Related Work

In the rest of this article, we use "graph" to refer to the topological structure with no associated attributes and "network" for a graph with an arbitrary number of attributes associated with its vertices and edges. "Vertices" and "edges" refer to topological features while "nodes" and "links" refer to their visual counterparts in node-link diagrams. For matrices, "rows" and "columns" refer to the visual representation of vertices and "cells" are the visual representation of edges.

2.1 Social Network Analysis

Social networks are graphs where the vertices are actors (people) and the edges are relationships. They vary from very sparse (genealogical trees) to very dense (exports and imports between countries). *Small-world networks* belong to an intermediate category that occurs very frequently in social networks, including many acquaintanceship networks as well as the global Internet. They are the focus of many studies [23, 20] because of their interesting properties [33]. For social network visualization, the most relevant of these properties are a high clustering coefficient, corresponding to the presence of many *locally dense* clusters, and a small cross-section, caused by a small number of hub vertices connecting communities in a graph that is *globally sparse*.

Social network analysis relies on three important tasks [31, 27]:

- (T1) identify *communities*, *i.e.* cohesive groups of actors that are strongly connected to each other;
- (T2) identify *central actors*, *i.e.* actors linked to many others or that bridge communities together;
- (T3) analyze roles and positions — these are higher level tasks relying on the interpretation of groups of actors (positions) and connection patterns (roles).

We now consider each of these three tasks in more detail, pointing out the corresponding graph-theoretic properties or graph analysis tasks using the taxonomy of tasks in [26].

To perform *community analysis*, an analyst should be able to group actors by attributes and study the connection patterns within each group. The analysis of attributes such as actors' names or interests is important to label the community in question and interpret why these actors are grouped. Studying the connection patterns reveals how actors of the community are linked and the strength of their relationships. Analysts need to evaluate the density of a community in terms of connections and also to quickly identify *cliques* (a group where each actor is linked to every other actor) and missing relationships. Thus, community analysis relies on attribute-based tasks, involving attributes of actors or relationships, and topology-based tasks, such as examining adjacency (direct connections) between nodes.

Identifying central actors is revealed by performing essentially topology-based tasks. Analysts need to identify the most connected actors, as well as articulation points (actors bridging communities together). Such actors can be identified using measures of centrality, several of which are based on path-related tasks. For example, the betweenness centrality indicates the number of times a node is present in a shortest path between every pair of nodes in the network. Identifying central actors requires understanding the global structure of the network, *i.e.* finding communities, how they are linked and what actors link them.

Analyzing roles and positions is done by analyzing how actors are connected within a community and outside a community. This task requires more interpretation and relies also on attributes of actors and relationships.

Many systems exist to analyze social networks. We classify them into two categories: menu-based systems and exploration systems.

Menu-based systems provide a wide range of functionality but users often need expert help or a cookbook to analyze their datasets. Examples of these systems include Ucinet [7] — based on statistics and proposing a broad range of analysis functions — and Pajek [8] which provides a large set of algorithms to partition, permute, cluster, hierarchize and layout networks.

Mastering all the richness of these menu-based systems to control the analysis process requires considerable effort from the user, hence recent systems are aimed at a more exploratory process. This process is based on starting with an overview of the whole network and then, using interaction (MatrixExplorer [16]) or simple scripts (Guess [2]), manipulating the dataset (*e.g.* through filtering or clustering) to create a set of visuals for further analysis. A number of recent systems forgo the first step of this process because displaying a readable overview of a large network is too difficult. PivotGraph [32] proposes starting the exploration from a top level aggregation of network attributes. The user visualizes categories and their relationships, and then interacts with the visualization to explore lower levels. NetLens [21] focuses on simple visualizations (histograms) of the network attributes and uses interaction to analyze the network. Semantic substrates [29] relies essentially on filtering and organizing actors according to their attributes. Finally, TreePlus [22] and Vizster [15] focus on a local representation of the network and use interaction to navigate within the whole dataset. These systems, while easy to use and sometimes engaging, are not effective at showing global structures of the network or global features such as central actors.

2.2 Graph Drawing

Graph drawing has a very rich history [9, 18], with early work on interactive computerized visualizations extending back to the 1960s [4]. However, almost all visualizations of graphs amount to either node-link diagrams or adjacency matrix representations. There are a few examples of hybrid representations for graphs [14, 30] and for trees [35, 12] but none so far have combined node-line diagrams with adjacency matrices.

Node-link diagrams are the most familiar representation of graphs in general and of social networks in particular. They are good at showing the overall structure of a sparse graph, but Ghoniem et al. [13] showed that density has a strong impact on readability in these diagrams. Focusing on basic readability tasks such as finding an actor or determining if two actors are linked, they conclude that node-link diagrams perform badly for dense networks even with few (*e.g.* 20) nodes. Because node-link diagrams become unreadable in dense communities and around high-degree hub nodes, they do not lend themselves to community analysis.

As an aside, in a community that is almost a clique and only missing a few edges, one might suggest using a "complementary" node-link diagram, where the links displayed indicate the *missing* edges; all the other edges being implicitly present. This would reduce clutter in some case, but in general is not a viable solution, because a community of n vertices with $n^2/4 = O(n^2)$ edges is considered dense, but has an approximately equal number of present and missing edges. Thus, clutter remains a significant problem even with such "complementary" node-link diagrams.

The adjacency matrix representation, which is particularly effective for dense graphs, have been proposed to solve this problem [1, 16]. However, it is ill-suited to path-related tasks [13] that are very important in social network analysis. Analysts following paths between actors using a node-link network representation can exploit "Gestalt continuation" preattentive visual processing, but in a matrix representation the same task requires aligning and matching nodes back and forth between corresponding rows and columns, a tedious and error-prone high-level cognitive task. So, matrix representations ease community analysis, but hinder identification of important global structures.

Thus, at one extreme are sparse social networks, which have an almost tree structure and few communities, for which node-link diagrams are well suited. At the other end of the spectrum are very dense networks in which matrices are well suited. The problem boils down to deciding which visualization is more suitable for small-world networks that have an intermediate nature, being globally sparse but locally dense. Choosing between these representations requires a trade-off between readability of global structure and ease of community analysis.

Henry and Fekete [16] chose to provide users with both representations, side-by-side, synchronized by brushing and linking. They argue that users can use the most appropriate visualization for each task. However, their system requires the use of two screens and the authors point out the potential cognitive load and divided attention from switching between representations.

Other recent work by Henry and Fekete [17] attempts to overcome the weaknesses of matrix representations by adding links on the sides of the traditional matrix. While the authors experimentally demonstrated that their visualization improves the traditional matrix, their results also show that the user fails to identify some important features, in particular, the articulation points of networks.

Solutions have also been proposed to improve the readability of node-link diagrams for communities. Auber et al. [3] introduce aggregated node-link diagrams where each community is aggregated in a single node within which a small overview is displayed. While communities are quickly identifiable and the global structure more readable, detailed analysis of communities is impossible because links between communities are missing.

Holten proposed the Hierarchical Edge Bundles technique [19] to improve the readability of hierarchical graphs; it can also be applied to clustered graphs. Although it can improve the readability of the global structure and inter-community relationships, it is still difficult to identify intra-community organization as nodes inside clusters are positioned along a circle, creating many link crossings.

3 NodeTrix

NodeTrix is a hybrid representation of networks based on the node-link diagram where communities can be represented as matrices. Intra-community relationships use the adjacency matrix representation while inter-community relationships use normal links.

3.1 Data Structure and Design Choices

Two networks are involved in a NodeTrix representation: the raw *underlying* network (composed of underlying nodes and links) that serves as initial input, and an *aggregated* network (composed of aggregated nodes and links) that is derived from the underlying network. Each aggregate node may correspond to either a unique underlying node or to a group of underlying nodes that typically form a community. Underlying nodes are never shared by aggregate nodes, *i.e.* there is a many-to-one mapping from underlying nodes to aggregate nodes (and also from underlying links to aggregate links.)

Because our goal with NodeTrix is to provide a readable representation for dense subgraphs, only a single level of aggregation is used: dense subgraphs are simply aggregated and displayed as matrices. Some aggregated nodes may correspond to only one underlying node rather than a group of underlying nodes and these are displayed as a simple node rather than a matrix. However, operations are designed to be uniform over all aggregated nodes. In particular, the user can add or merge aggregated nodes, whether each node involved corresponds to just one or many underlying nodes.

Attributes of the underlying nodes and underlying links are combined and propagated up to the aggregated elements. For nominal attributes, values are combined through simple concatenation. Numerical attributes are aggregated either using the average, the min or the max values. An interesting benefit of using matrices in NodeTrix is that they can display the attributes of both underlying elements and aggregated elements, for both links and nodes. Furthermore, because users can dynamically switch between the two representations, more visual variables are available to show attributes. For example, the background color of a matrix can correspond to an aggregated node attribute, while attributes of each underlying node can be shown along the *axes* (the sides) of the matrix. Similarly, the axes can be used to display labels of individual underlying nodes, while a global aggregated node label is also shown.

3.2 NodeTrix Visualization

To render the NodeTrix representation, a standard node-link layout is used for the aggregated graph, and in addition aggregated nodes containing more than a single underlying node are overlaid with a matrix representation.

3.2.1 Drawing Matrices

NodeTrix is built using the InfoVis Toolkit [10] and uses its rendering mechanism to create the visualization. The rendering mechanism involves a pipeline of renderers which makes it simple to draw a matrix over a standard node. For example, a simple rendering pipeline for a node-link diagram would be: compute_position, compute_size, set_color, fill_shape, draw_border, draw_label. To overlay matrices on standard nodes, we introduced a matrix renderer between the fill_shape and the draw_border renderers. This renderer displays the matrix after having rendered the background node (with a given position, size and color) and before drawing the border used for selection and the label.

Matrices have two advantages which make them more readable than node-link diagrams to represent an aggregated node: first, as nodes are placed linearly, links from the rest of the network to the underlying nodes are readable and only suffer from a limited number of crossings; secondly, as nodes are represented both in rows and columns, links can be drawn from any of the four sides of the matrix, which also reduces crossings and overlapping problems. Finally, rows and columns of matrices can be reordered (manually or automatically) to improve readability and further reduce the number of edge crossings.

To save memory and allow the user to control all the matrices' properties with a single general control panel, the matrix renderer uses a single matrix visualization object, applying a different permutation and filtering for each aggregated node. Therefore, changing the color attribute for the matrix axes will affect all displayed matrices. We considered creating a separate matrix object for each aggregated node instead, allowing the user to display different attributes on different matrices. However, it would have been very confusing for the user to manage all the controls in a single huge panel (one set of controls for each matrix) or to force the user to select a matrix to see its controls. We decided that sharing the visual attributes for all the matrices was the best option.

3.2.2 Drawing Links

To display links in NodeTrix, we considered three options: displaying only aggregated links, displaying only the underlying links, or displaying both.

Displaying aggregated links (Figure 2a) provides simple visual feedback on how communities interact. Moreover, an aggregated attribute can be mapped to a visual variable (*e.g.* color, thickness, opacity) of this link. However, the details of which actors of the two communities are interacting are not visible. On the other hand, displaying each underlying link (2b) provides connectivity details and enables visualization of the attributes of each link independently, but at the cost of many more links and potential crossings. Because small-world networks are globally sparse, they have few inter-community relationships. However, displaying both aggregated and underlying links at the same time could be confusing, due to the possible interaction between visual variables and link crossings or overlap.

We chose to visualize underlying links, but with the added flexibility of allowing the user to control the thickness of the links through a slider. Increasing the thickness of the underlying links eventually causes them to merge, and the resulting visual feedback (2c) is similar to visualizing aggregated links (2a) with increased precision. Moreover, when an underlying link attribute has a color, the thickness of the blended bands of color represents the number of underlying edges (2d). The slider that interactively controls the thickness updates the visualization with smooth, immediate feedback. Manipulating this slider allows the user to quickly switch from one kind of overview mode — How are communities linked? What kinds of links? — to a detailed mode — Who link the communities together?

3.2.3 Layout

Because the aggregated network in NodeTrix is laid out as a traditional node-link diagram, any existing graph layout could be used. However, because NodeTrix is intended to be used as an interactive exploration tool and we do not want to confuse the user with large, sudden changes to the layout, it seems appropriate to support incremental, interactively-driven changes to the layout, such as aggregating or splitting nodes. The initial layout computed for the graph is Noack's [24] LinLog layout, chosen to give prominence to clusters so they can be quickly identified. After this initial layout step, the user may make local changes by dragging nodes to change their positions, grouping a set of nodes, or removing a node from a group.

To (re)order the nodes within an adjacency matrix, many different algorithms can be used. As these matrices are typically small, the running time is not an issue. Nevertheless, we chose not to reorder the matrices automatically as they are usually very dense and do not need any particular optimization. Instead, we preferred to allow the user to interactively move rows and columns.

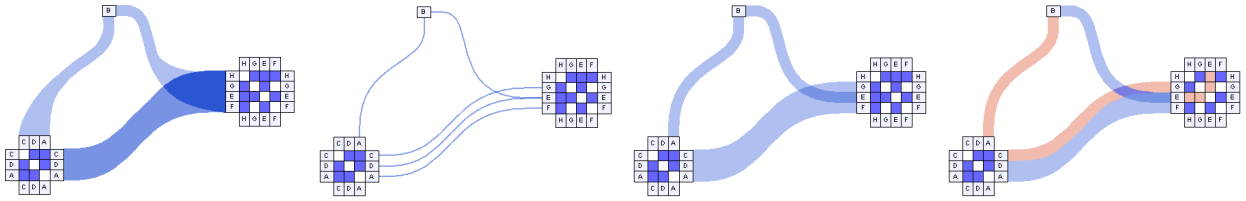
3.3 Visual Variables and Control Panel

NodeTrix relies on the InfoVis Toolkit to generate controls to filter and affect visual variables. The user controls two sets of visual variables: one for the node-link diagram, and one for the matrices displayed in the aggregated nodes. Both sets of variables consist of the following, for nodes and links: color, transparency, shape size, filled area of the shape, border color, width, and labels.

The user filters and associates visual variables to aggregated and underlying network attributes using simple controls such as combo boxes or sliders. The visualization is immediately updated, following the principles of direct manipulation [28].

4 Interaction

We designed a set of interaction techniques to create, edit and manipulate NodeTrix in a very simple and powerful way because we believe that manipulation is key to understanding a network and its potential multiple interpretations.



(a) Aggregated links (b) Underlying links (c) Underlying links with full size (d) Underlying links with attributes

Fig. 2: Drawing links

4.1 NodeTrix Editing

NodeTrix can be created starting with a pure, traditional node-link diagram. We propose a set of interactions based on dragging and dropping nodes, matrix axis items, and matrix core elements (cells). We feel these interactions are easy to understand as the user simply grabs one of these elements and drops it to another location (possibly over existing elements) to perform an action. When dragging an element, the user has immediate visual feedback and is able to read the element's label.

Moving a node or a matrix to adjust its position and improve the readability of the representation can be done by grabbing the matrix or the node, dragging it and releasing it at a new position. As the element is dragged, its connecting links are updated.

To *aggregate a group of nodes* into a matrix, the user may lasso-select the desired nodes, which are then immediately converted into a matrix. To make the transition to a matrix smooth, the transformation from node-link diagram to matrix is animated. The animation speed is adjustable to suit both novice users (who may benefit from seeing a slow animation, to better understand how nodes and edges become organized into a matrix) and advanced users (who would presumably prefer a brief animation). *Splitting a matrix* back into a group of nodes is done by right-clicking on it, in which case nodes are positioned with a circular layout around the center of the previous matrix.

To complete these basic aggregation features, we provide additional interactions for finer-grain editing of the aggregated elements. If users missed an element with the lasso selection or simply wants to *add an additional node* to a matrix, they can drag-and-drop a single node into the matrix. The node will integrate with the matrix, appearing in the matrix axis items (in both the rows and columns). Its connections with the matrix elements will be displayed in the matrix core, whereas its connections with the external elements will be displayed as links starting from the matrix axis items and ending at the external elements. If a single node is dragged onto another single node, then the two will be aggregated into a 2×2 matrix. On the other hand, if users wish to *extract a node* from a matrix, they can grab the corresponding matrix axis item (either on the row or column axis) and drop it outside the matrix. The dropped item will then be displayed as a standard node with appropriate links between itself and the matrix, and the corresponding row and column in the matrix will be removed.

To increase readability or visualize different combinations, users may want to *move an item* from one matrix to another. This can done by grabbing a matrix axis item and dropping it on the other matrix. During the transfer, the user is able to read the node label and may cancel the interaction by dropping the element back into the original matrix. This may result in a change to the ordering of nodes in the matrix. The *order of items* in the matrix normally corresponds to the item addition order, with the last item added in the last position. However, when two matrices are merged, the item ordering follows the indices of nodes in the underlying network. The ordering of nodes can be changed by grabbing nodes and dropping them back into the matrix, one at a time, in the desired order.

Finally, users can *merge matrices* together by dragging-and-dropping a matrix over another.

4.2 Geometric Zoom on Matrices and Axis Labels

An aggregated matrix may occupy more space than the original group of nodes in node-link representation. This is partly due to the labels displayed on each side of the resulting matrix. However, while reading labels on each side of the matrix is required to perform community analysis and local editing operations, the axis labels are not required on all matrices at all times, and the size of the matrix core can be reduced to fit the minimum level of readability. Moreover, as each matrix possesses a label (reflecting its composition), axis labels for individual underlying nodes may not be necessary at all in a final layout.

We tried displaying the axis labels on demand following the excentric label principles [11]. For example, if the mouse pointer hovered over a matrix, its axis labels as well as its neighbors' axis labels would be displayed. In this case, axis labels needed to remain visible after the mouse pointer moved (to avoid frustrating the user by losing a landmark when pointing at another item). However, during a case study, we observed that it was more comfortable to be able to read all axis labels when editing, and to remove all axis labels at once and reduce the size of the matrices to get an overview of a final layout.

For these reasons, we added two sliders in the control panel to control the size of the matrices and the axis labels.

4.3 Supporting the Exploration of Matrices

One weakness of the matrix representation, when exploring a network, is the tedious work required to perform path-related tasks. For example, finding how two communities are connected is tedious as it requires going back and forth alternately reading rows and columns. Moreover, if communities are far apart in the matrix, this task requires a scan of the full length of matrix rows or columns, and connections in a large matrix may lie outside the viewport. Obviously, the task is worse when dealing with three matrices as the user needs to check for intersections of rows and columns in each of the three communities.

We noticed in a participatory-design session reported in [16] that social network analysts also use the matrix representation for some of their analyses. To help perform community analysis and provide support for path-related tasks in general, we provide users with a couple of interaction techniques that work across separate matrix-NodeTrix windows, that might be arranged in a dual-viewport or split-screen fashion. These techniques are still based on drag-and-drop, however this time, the user drags a group of elements from one window to another one.

The interaction is made of two steps: first, the user selects a group of nodes in the window of the pure matrix visualization and then drags this group to the NodeTrix window. To select the group of nodes, we provide lasso selection directly on the pure matrix representation. Alternatively, the selection can be done on an axis (rows and columns). When a group of cells is selected, the corresponding set of vertices transferred is the union of the edges' source vertices and sink vertices. Dropping the selected group inside the NodeTrix window performs the addition of an aggregated node to the NodeTrix visualization. The group is then displayed as a matrix. Selecting and dropping a second group allows the user to see how these groups are connected to each other visualizing the result with links. The process can continue to visualize connections between several communities.

5 Animation

Proper use of animation has much potential to increase the effectiveness of user interfaces and visualizations [34, 5, 6]. To help users maintain their mental model of the network across interactions, we considered how to continuously animate the aggregation of nodes into an adjacency matrix. Typically, animating over transitions involves some kind of interpolation of graphical elements from one state to another. In the case of transitioning from a node-link diagram to a matrix, however, the visual design of the animation is non-trivial, because node-link diagrams and adjacency matrices are composed of very different graphical elements. There is a sort of duality between the two forms: nodes correspond to *points* in node-link diagrams, but to *line segments* (rows and columns) in matrices, and, conversely, edges correspond to *line segments* in node-link diagrams, but to *points* (intersections of rows and columns) in matrices. The key problem is to find an intermediate graphical form or layout through which we can interpolate during an animation.

To find solutions, we conducted sessions of sketching, brainstorming, and analysis of how networks can be depicted with node-link diagrams and matrices. We noticed that, although each node corresponds strictly to an entire row and column within a matrix, the node can also be identified with special points in the matrix, that occur where the diagonal and the axes (or sides) of the matrix intersect the node's row and/or column. Furthermore, it is possible to draw a node-link diagram overlaid on a matrix grid, in such a way that the nodes fall on some of these special points, and such that the edges (drawn as poly-lines or curves) pass through their own corresponding locations in the matrix. Figure 3, sub-figures 3–7, show some possibilities.

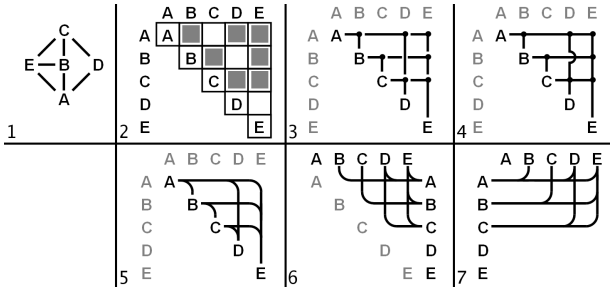


Fig. 3: 1: A node-link diagram of a network. 2: The corresponding adjacency matrix. For simplicity, only the upper half is shown, since the matrix is symmetric. 3 through 5: different ways of depicting the edges in a node-link diagram laid out over the matrix, using poly-lines or curves. The "corners" of the edges coincide with the filled-in cells of the matrix in 2. 3 and 4: inspired by circuit wiring diagrams. 5 through 7: different choices for the locations of nodes in the node-link diagram laid out over the matrix. 6 and 7: each node is duplicated and has two locations in the node-link diagram.

As can be seen, there are several possibilities for the intermediate state that an animation might interpolate through. We identify a few different design dimensions. First, the edges in the intermediate state might be depicted using poly-lines or curves (Figure 3, sub-figures 3–5). Second, the location of nodes might be along the diagonal or along the sides of the matrix (sub-figures 5–7); in the latter case, each node must be duplicated at some point during the animation. (We also note that a simple calculation shows that the average length of links in sub-figures 5, 6, and 7, for large matrices, is 1/3, 1/3, and 1/2 of the side of the matrix, respectively; so 5 and 6 minimize average link length.) Third, the intermediate state might show only the upper half of the matrix (after which the animation might fade in or unfold the other half of the matrix as a mirror image), or the intermediate state might show the whole matrix (before which the animation would have to duplicate the edges somehow, since they occur in each half of the matrix).

We made a first set of choices along each of these design dimensions and implemented an animated transition from node-link diagrams to adjacency matrices, both in the NodeTrix software and in an additional piece of software. Figure 4 shows the latter implementation, where the network has colored nodes and edges. As can be seen, the intermediate state (sub-figure 3) shows both halves of the matrix, hence the animation begins by duplicating edges (sub-figure 2). The positions of the nodes, and of the control points for the edge curves, are gradually interpolated to reach their final locations (sub-figure 3). Then, the edge curves are faded out as the normal depiction of the matrix is faded in (sub-figure 4). Notice that the "corners" of the edge curves coincide with the appropriate cells of the matrix (sub-figure 4), and the opacity of the curves is varied such that these corners are the last part of the curve to fade away, to reinforce their visual correspondence to the matrix cells that fade in.

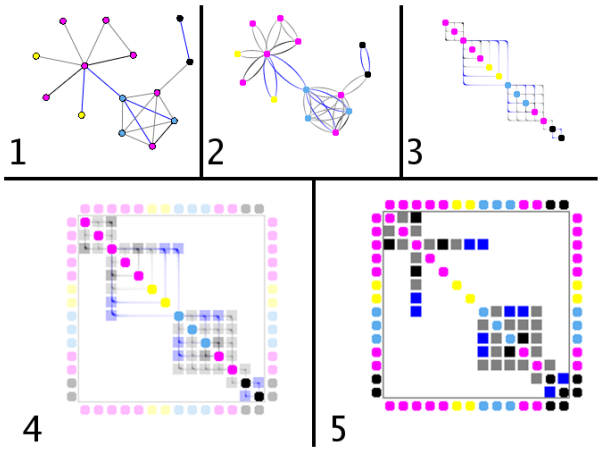

Fig. 4: The stages of an animation from a node-link diagram (1) to an adjacency matrix (5). Figure 3, sub-figure 5 was chosen as the intermediate form through which we interpolate.

Compared with other animated transitions in visualization systems, this animation may seem rather complicated, and in practice an expert user may prefer that the animation be brief (e.g. lasting 0.5 seconds). However, novice users may appreciate having these animations last longer, at least initially. We expect that, in addition to helping the user maintain a mental model of the visualization across transitions, these animations may also have an educational benefit, to help users learn how adjacency matrices are constructed and how to interpret them. We expect it would be worthwhile to implement variations on the animation corresponding to the other design choices we identified, and to solicit feedback from users as to their preferences.

A fourth design dimension relevant for education involves deciding whether to animate all the nodes and edges at the same time, or to animate them in sequence. For example, edges might be animated one at a time, constructing the matrix cell-by-cell, or alternatively, each node (with all its edges) might be animated one at a time, constructing the matrix row-by-row. Such a sequential animation might be made to accelerate as more of the matrix is built-up, allowing the user to see the process in detail at first, and then to see it quickly complete the rest of the matrix.

6 Case Study: Exploring and Presenting Publications Data

In this case study, we present how NodeTrix can be used both for exploring and presenting publications data. We also show how this representation can tackle the three important tasks for social network analysis (identify communities (T1), identify central actors (T2), and analyze roles and positions (T3)). The InfoVis 2004 contest [25] provided us with a clean dataset from which we extracted the co-authorship network of the Information Visualization field. This network is disconnected into 291 components and contains 1104 vertices (researchers) and 1787 edges (co-authorship). It has a low density and a high clustering coefficient, making it a small-world network.

We only present here the analysis of the largest connected component, containing 122 vertices and 311 edges. This network could be considered small, but it already presents challenges for exploration and presentation using traditional matrix and node-link diagrams. Detailed communities are not readable in node-link diagrams, while finding connections between communities is tedious in matrices.

Moreover, presenting results on paper generally requires some filtering when using either pure matrices or pure node-link diagrams. The matrix representation requires space that grows quadratically with the number of nodes: it cannot fit in a printed article with readable labels for networks of more than about a hundred nodes. On the other hand, edge-crossings and node-overlap are issues with node-link diagrams. Thus, with these traditional non-hybrid represenentations, filtering is required to reduce the size and density of the network to make it more readable. Using NodeTrix solves these presentation problems since dense subgraphs are aggregated as matrices, completely eliminating edge-crossings and node-overlap in those portions of the network. Furthermore, communities (aggregated nodes) remain readable.

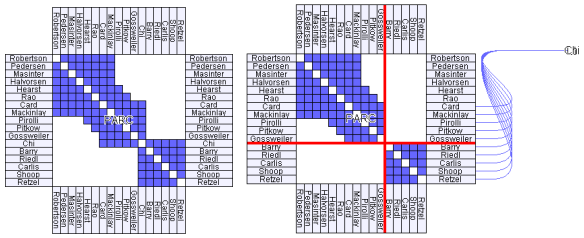
6.1 Setup

To manipulate NodeTrix, we used an interactive pen display. Pen-based interactions on NodeTrix are intuitive and comfortable using this input device. The user can simply grab elements by pressing the pen over them, drag them moving the pen on the screen and finally release them by raising the pen. Lasso selection provides also a very intuitive feedback similar to the use of a real pen.

6.2 Aggregation and Exploration

NodeTrix is a flexible representation for which the level of aggregation as well as the level of details is controllable. For example, Figure 7 and Figure 1 show almost the same dataset: the largest component of the InfoVis co-authorship network. We removed a couple of authors in Figure 7 as we found them duplicated in the dataset. In the compact representation (Figure 1), the goal was to provide a brief overview of main communities in the field (T1), whereas in the second representation, the goal was to be able to identify all nodes of the network including actors bridging communities together (T2). In both representations, patterns of connections inside matrices and between them are readable (T3).

While exploring the network, the interactions provided with NodeTrix ease the analysis. For example, moving an actor in and out of a community (matrix) helps clarify his influence on this community (T2, T3). Figure 5 illustrates this operation, showing that if Ed Chi is extracted from the PARC community, then the community is disconnected. This operation also helps clarify the matrix representation to novice users, as they can drag each actor out of the matrix, one at a time, comparing the visualization of his relationships within and outside the matrix representation.



(a) PARC Community (b) Ed Chi's influence

Fig. 5: Moving a node in and out of a matrix. In the second case, red lines indicate that the matrix is disconnected in two groups (upper left and lower right). Ed Chi is the bridge between these two groups.

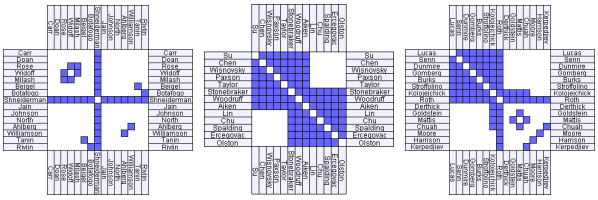
6.3 Patterns of Collaboration

The main result of our case study is the identification of different collaboration patterns: cross patterns and block patterns (T1, T3).

Figure 6a reveals the collaboration pattern of Ben Shneiderman, main actor of the InfoVis field. This aggregated matrix is very sparse and shows only a complete row and column. We named this pattern a cross pattern because if Shneiderman is placed almost anywhere in the matrix (except on the first and last rows-columns), the visible pattern is a large cross. This pattern reveals that Shneiderman collaborates with all researchers in this matrix. However, the low density shows that Shneiderman's collaborators generally do not work together: they are perhaps students he has supervised. Figure 1 reveals several matrices with this pattern of collaboration: Plaisant et al., Bederson et al., and Eick et al.

Figure 6b reveals the collaboration pattern of researchers from Berkeley. The aggregated matrix is almost a clique, it is a very dense community. Contrary to the previous pattern, this one reveals researchers strongly collaborating with each other rather than only a single one. Figure 1 shows that PARC has the same collaboration pattern.

Note that the community formed by Stephen Roth is in an intermediate category (Figure 6c). Roth is central in this community, but a large block is also visible, meaning that some researchers also collaborate with each other.



(a) Cross pattern (b) Block pattern (c) Intermediate pattern

Fig. 6: Three collaboration patterns: (a) Shneiderman and his collaborators, (b) Researchers at Berkeley, (c) Roth and his collaborators at CMU.

7 Conclusion and Future Work

We have introduced a novel visualization called *NodeTrix*. This representation integrates the best of two traditional network representations: node-link diagrams and adjacency matrix-based representations. The strength of this representation for analyzing social networks is in combining the familiarity of node-link diagrams to understand the global structure of the network with the readability of matrices for detailed community analysis.

We described a set of interactions to support the manipulation of NodeTrix and help analyze networks. We also proposed an animation for smoothly transitioning between node-link diagrams and matrices. In a slower mode, this animation can be used to help novice users understand how matrices work. Finally, we have illustrated the effectiveness of NodeTrix with a case study of the InfoVis publications data.

We have already collected very positive feedback from our group of users as well as from external analysts. We plan to extend our system in several directions and to perform formal evaluations on its use with analysts. The interactive capabilities of NodeTrix are well suited to collaborative analysis so an obvious extension includes collaborative editing, either through the network or in a shared environment with large displays.

We have iterated on several alternative representations to visualize social networks and believe that NodeTrix is among the most effective and simplest to understand. We plan to run further experiments to quantitatively demonstrate its efficiency compared to state-of-the-art representations. NodeTrix will be released as a component of the InfoVis Toolkit (`ivtk.sourceforge.net`).
