**Abstract.** Distributed systems and applications require efficient and effective techniques (e.g. self-(re)configuration, self-healing, etc.) for ensuring safety, security and more generally dependability properties, as well as *convergence*. The complexity of these systems is increased by features like dynamic (changing) topology, interconnection of heterogeneous components or failures detection. This paper presents a methodology for verifying protocols and satisfying safety and convergence requirements of the distributed self-\* systems. The self-\* systems are based on the idea of managing complex infrastructures, software, and distributed systems, with or without minimal user interactions. *Correct-by-construction* and *service-as-event* paradigms are used for formalizing the system requirements, where the formalization process is based on incremental refinement in EVENT B. Moreover, this paper describes a fully mechanized proof of correctness of the self-\* systems along with an interesting case study related to the P2P-based self-healing protocol.

**Keywords:** Distributed systems, self-\*, self-healing, self-stabilization, P2P, EVENT B, liveness, *service-as-event* 

# 1 Introduction

Nowadays, our daily lives are affected by various advanced technologies including computers, chips, and smart-phones. These technologies are integrated into distributed systems with different types of complexities like mobility, heterogeneity, security, fault-tolerance, and dependability. Distributed systems are largely used in many applications and provide required functionalities from the interactions between a large collection of possibly heterogeneous and mobile components (nodes and/or agents). Within the domain of distributed computing, there is an increasing interest in the self-stabilizing systems, which are able to autonomically recover from occurring the faults [7]. The autonomous property of the self-\* systems tends to take a growing importance in the analysis and development of distributed systems. It is an imperative that we need to get a better understanding of the self-\* systems (emergent behaviours, interactions between agents, etc.), if we want to reason about their security, correctness and trustworthiness.

<sup>\*</sup> The current report is the companion paper of the paper [4] accepted for publication in the volume 8477 of the serie Lecture Notes in Computer Science. The Event-B models are available at the link http://eb2all.loria.fr. Processed on July 3, 2014.

Fortunately, the formal methods community has been analysing a similar class of systems for years, namely distributed algorithms.

In this study, we use the *correct by construction* approach [12] for modelling the distributed self-\* systems. Moreover, we also emphasize the use of the *service-as-event* [3] paradigm, that identifies the phases of *self-stabilization* mechanism, which can be simplify into more stable and simple coordinated steps.

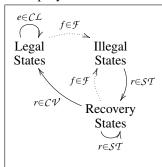

Fig. 1: Diagram for a Self-Stabilizing System S

We consider that a given system S (see in Fig.1) is characterized by a set of *events* (*procedures* modelling either phases or basic actions according to an abstraction level) that modifies the state of the system. *Legal states* (correct states) satisfying a *safety property P* are defined by a subset CL of possible events of the system S. The events of CL represent the possible big or small computation steps of the system S and introduce the notion of *closure* [5], where any computation starting from a *legal state* satisfying the *property P* leads to another *legal state* that also satisfies the property P. The occurrence of a fault f leads the system S into an *illegal state* (incorrect state), which violates the property P. The fault f is defined as an

event f that belongs to a subset  $\mathcal{F}$  of events. When considering the hypothesis of having a self- $\star$  system, we assume that there are *procedures* (protocols or actions) which implement the identification of current illegal states and recovery for legal states. There is a subset  $\mathcal{ST}$  of events modelling recovery phases for demonstrating the stabilization process. The system recovers using a finite number of stabilization steps (r). The process is modelled as an event r of  $\mathcal{CV}(\subseteq \mathcal{ST})$  eventually leading to the legal states (convergence property) from recovery states. During the recovery phase, a fault may occur (see dotted transitions in Fig.1).

The system S can be represented by a set of events  $\mathcal{M} = \mathcal{CL} \cup \mathcal{ST} \cup \mathcal{F}$ , where the model  $\mathcal{M}$  contains a set  $(\mathcal{CL})$  of events for representing the *computation steps* of the system S. When a fault occurs, a set (ST) of events *simulates* the *stabilization* process that is performed by S. The formal representation expresses a *closed* model but we do not know what is the complete set of events modelling faults/failures. We characterise the fault model in a very abstract way and it may be possible to develop the fault model according to the assumptions on the environment, but we do not consider this in the current study. We restrict our study by making explicit the events of ST modelling the *stabilization* of the system from illegal/failed states. We ensure that the *convergence* is always possible: a subset CV of ST eventually leads S into the *legal states* satisfying the invariant P of the system. Whenever the system S is in a *legal state*, we consider that the events of ST are either not operative or simply preserve the invariant P of the system.

In the previous paragraph, we name *procedures* ( *protocols* or *actions*) by the term *events*. An *event* is modelling a process which is defined by its pre and post specifications or a state transformation belonging to a larger process. It means that we need to play with abstraction levels to develop a self-\* system. For instance, one can state that an event called stabilise is ensuring the functionality of getting a stable system (the *what*) without giving details of the detailed process itself (the *how*). Hence, the notion of

event is identified to an abstraction level and can be either modelling a global process (the *what*) or a local update of a variable (the *how*). We formalise the system S using the EVENT B modelling language [1], dealing with *events* and *invariant* properties including *convergence* properties by using a temporal framework. The *service-asevent* paradigm [3] helps to express this *concretisation* process: the procedures (1) *leading* from the *illegal states* to the *recovery states*, and (2) *leading* from the *recovery states* to the *legal states* are stated by (abstract) events, during the first stages of the EVENT B development. The next step is to unfold each (abstract procedure) event, by refinement, to a set of coordinated and concrete events, which form the body of the procedure.

This paper is organised as follows. Section 2 presents related works. Section 3 introduces the EVENT B modelling framework including *service-as-event* paradigm and a formal definition of self-\* systems. Section 4 presents the formal verification approach and illustrates the proposed methodology with the study of the self-healing P2P-based protocol [14]. Section 5 discusses on approaches for studying temporal properties for EVENT B models. Finally, Section 6 concludes the paper along with future work.

### 2 Related Works on Formal Modelling for Self-⋆ Systems

Systems usually run in intricate environments, with frequent and unexpected changes. This feature increases interest towards autonomous and self-\* architectures, as they are able to adapt themselves according to the changes that may occur in the systems (faults, etc.) or in the environment. Applying formal methods to self-\* systems originates from the needs of understanding how these systems behave and how they meet their specifications. A self-\* system relies on *emergent behaviours*, resulting from interactions between components of the system [21].

Traditionally, the correctness of self- $\star$  and autonomous systems is validated through the simulation and testing [20, 22]. However, simulation and testing are not sufficient to cover the whole set of possible states of a system [2]. Therefore, formal methods appear as a promising land for validating self- $\star$  systems, as long as formal techniques can assert the correctness of these systems and certify target properties, like trustworthiness, security, efficiency, etc. under the rigorous mathematical reasoning [6, 8, 24].

Smith et al. [21] have applied the stepwise refinement using Z to study a case of self-reconfiguration, where a set of autonomous robotic agents is able to assemble and to reach a global shape. They do not validate models using an adequate tool (e.g. proof checker, proof assistant, etc.) and models are not localized. Calinescu et al. [6] have used Alloy to demonstrate the correctness of the autonomic computing policies (ACP). However, Alloy does not provide a mechanism for expressing the *correct-by-construction* paradigm. Méry et al. [2] have also investigated a self-reconfiguring system (Network-on-Chip: adaptative XY routing) using the EVENT B framework and the *correct-by-construction* approach.

State exploration approaches such as model-checking are also used to study self-\* systems. Model-checkers like SPIN, PRISM, SMV, UPPAAL are used for properties specification and getting evidences that properties, such as flexibility, robustness of the self-\* systems hold [6, 8, 10, 24]. Moreover, these tools allow users to obtain the metrics

for the self-\* systems, such as performance, and quantitative evaluations [6, 8, 10, 24]. Model-checking and state-space evaluation can be used during the conception of self-\* systems, but they are especially used for runtime verification [10, 24]. The limit of model checking is clearly the size of models.

Other formal techniques like static analysis and design by contract are also applied for the formal specification of self-\* systems [23]. These techniques are mainly used for *runtime verification*. Graphical approaches, such as Petri Nets, are used to model the temporal aspects and communication flows between different components of a self-\* system, and helped to study the cases like self-reconfiguration (replacement of a component, removal of a link between two components, etc.) [24].

Finally, graphical notations (e.g. UML) help to represent self-\* systems with understandable figures [25]. Their general purpose is to provide users an insight of a self-\* system by describing its architecture, the relationships between agents of the system (OperA methodology [17], ADELFE [20]) or by presenting the system as a composition of extendable/instantiable primitives (FORMS [25]). These notations are generally graphical front-ends for the more complex representations of self-\* systems, where the source code [20], and formal models [25] can be generated from the notations.

Our proposed methodology integrates the EVENT B method and elements of temporal logics. Using the refinement technique, we gradually build models of self-\* systems in the EVENT B framework. Moreover, we use the *service-as-event* paradigm to describe the *stabilization* and *convergence* from *illegal* states to *legal* ones. Self-\* systems require the expression of traces properties like liveness properties and we borrow a minimal set of inference rules for deriving liveness properties. The concept of *refinement diagrams* intends to capture the intuition of the designer for deriving progressively the target self-\* system. The RODIN platform provides a laboratory for checking, animating and validating the formal models.

#### 3 Modelling Framework

#### 3.1 EVENT B

We advocate the use of *correct-by-construction* paradigm for modelling the self-\* systems. The key concept is the incremental refinement (simulation) which provides link between discrete models by preserving properties. The EVENT B modelling language designed by Abrial [1] is based on *set theory* and the *refinement* of models: an abstract model expressing the requirements of a given system can be verified and validated easily; a concrete model corresponding to the actual system is *constructed* progressively by *refining* the abstraction. EVENT B is supported by a complete toolset RODIN [19] providing features like refinement, proof obligations generation, proof assistants and model-checking.

**Modelling Actions over States** The EVENT B modelling language can express *safety properties*, which are either *invariants* or *theorems* in a model corresponding to the system. Two main structures are available in EVENT B: (1) Contexts express static

informations about the model (for instance, graph properties as connectivity); (2) Machines express dynamic informations about the model, safety properties, and events. An EVENT B model is defined by a context and a machine. A machine organises events (or actions) modifying state variables and uses static informations defined in a context. An EVENT B model is characterised by a (finite) list x of state variables possibly modified by a (finite) list of *events*. An invariant I(x) states properties that must always be satisfied by the variables x and maintained by the activation of the events. The general form of an event e is as follows: ANY t WHERE G(t,x) THEN x: |P(t,x,x')| END and corresponds to the transformation of the state of the variable x, which is described by a before-after predicate BA(e)(x,x'): the predicate is semantically equivalent to  $\exists t \cdot G(t,x) \land P(t,x,x')$  and expresses the relationship linking the values of the state variables before (x) and just after (x') the execution of the event e. Proof obligations are produced by RODIN, from events: INV1 and INV2 state that an invariant condition I(x) is preserved; their general form follows immediately from the definition of the before-after predicate BA(e)(x,x')of each event e; FIS expresses the feasibility of an event e, with respect to the invariant I. By proving feasibility, we achieve that BA(e)(x,z) provides a next state whenever the guard grd(e)(x) holds: the guard is the enabling condition of the event.

| INV1 | INV2 | FIS |  $Init(x) \Rightarrow I(x) \mid I(x) \land BA(e)(x,x') \Rightarrow I(x') \mid I(x) \land grd(e)(x) \Rightarrow \exists z \cdot BA(e)(x,z)$ 

**Model Refinement** The refinement of models extends the structures described previously, and relates an abstract model and a concrete model. This feature allows us to develop EVENT B models of the self- $\star$  approach gradually and validate each decision step using the proof tool. The refinement relationship is expressed as follows: a model *AM* is refined by a model *CM*, when *CM simulates AM* (i.e. when a concrete event *ce* occurs in *CM*, there must be a corresponding enabling abstract event *ae* in *AM*). The final concrete model is closer to the behaviour of a real system that observes events using real source code. The relationships between contexts, machines and events are illustrated by the following diagrams (Fig. 2), which consider refinements of events and machines.

Fig. 2: Machines and Contexts relationships

The refinement of a formal model allows us to enrich the model via a step-by-step approach and is the foundation of our correct-by-construction approach [12]. Refinement provides a way to strengthen invariants and to add details to a model. It is also used to transform an abstract model to a more concrete version by modifying the state description. This is done by extending the list of state variables (possibly suppressing some of them), by refining each abstract event to a set of possible concrete versions, and by adding new events. We suppose (see Fig. 2) that an abstract model AM with variables x and an invariant I(x) is refined by a concrete model CM with variables y. The abstract state variables, x, and the concrete ones, y, are linked together by means of a, so-called, gluing invariant J(x,y). Event ae is in abstract model AM and event ce is in

concrete model *CM*. Event *ce* refines event *ae*. BA(ae)(x,x') and BA(ce)(y,y') are predicates of events *ae* and *ce* respectively; we have to discharge the following proof obligation:  $I(x) \wedge J(x,y) \wedge BA(ce)(y,y') \Rightarrow \exists x' \cdot (BA(ae)(x,x') \wedge J(x',y'))$ 

Due to limitations on the number of pages, we have briefly introduced the EVENT B modelling language and the structures proposed for organising the formal development. However, more details are available in [1] and on the Internet<sup>1</sup>. In fact, the refinement-based development of EVENT B requires a very careful derivation process, integrating possible *tough* interactive proofs. For assisting the development of the self-\* systems, we use the *service description* and *decomposition* that is provided by the *service-as-event* [3] paradigm (derived from the *call-as-event* approach [15]).

#### 3.2 The Service-as-Event Paradigm

This section introduces the *refinement diagrams* [3, 15] and presents the *service-as-event* paradigm. A brief overview on the usage of these formalisms for modelling the self-\* systems is given.

**Objectives** The *service-as-event* paradigm [3, 15] is a semantical extension of EVENT B and introduces a way to deal with liveness properties and traces, for modelling the self-\* systems.

**A Definition of Self-\* Mechanism** We characterize a self-stabilizing system S (more generally a self-\* system) by its ability to recover autonomously from an *illegal* (faulty) state (violating the invariant P of the system) to a *legal* (correct) state statisfying the invariant property P of system S. Temporal logic [3,11,15,18] can be used to describe such mechanism, using the liveness properties: we represent the *stabilization* (especially the *convergence*) property as a *service* where a system S, in an *illegal* state (characterized by  $\neg P$ ), reaches *eventually* a *legal* state (satisfying P). This service is expressed, with the *leads to* ( $\leadsto$ ) operator, as follows: ( $\neg P$ )  $\leadsto$  P. This *leads to* property (equivalently ( $(\neg P) \Rightarrow \diamond P$ )) states that every *illegal* state (satisfying  $\neg P$ ) will *eventually* (at some point in the future) lead to a *legal* state (satisfying P).

We define a temporal framework for the EVENT B model M of the studied system S by the following TLA specification: Spec(M):  $Init(y) \land \Box[Next]_y \land L$ , where Init(y) is the predicate specifying initial states;  $Next \equiv \exists e \in E.BA(e)(y,y')$  is an action formula representing the next-state relation; and L is a conjunction of formulas  $WF_y(e)$ : we express a *weak fairness* assumption over each event e modelling a step of the recovery process (we do not add any fairness on events leading to *illegal states* (*faults*)).

<sup>1</sup> http://lfm.iti.kit.edu/download/EventB Summary.pdf

Refinement Diagrams We express the self-\* mechanism using EVENT B, together

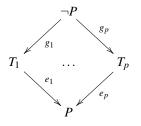

Fig. 3: A Refinement Diagram

with liveness properties under fairness assumptions. *Refinement diagrams* (see in Fig.3), introduced by Méry et al in [3, 15], allow to develop EVENT B models and add control inside these models. They are also used for stating (proofs of) liveness properties (under fairness assumptions), and for supporting refinement. Therefore, these diagrams are suitable for representing the models of self- $\star$  systems. A *refinement diagram* D = PD(M) for a machine M is the defined as a follows:

for a machine M is defined as follows: PD(M) = (A, M, G, E), where A is a set of assertions, G a set of assertions for M called conditions/guards of the form g(x), E is the set of events of M. The diagram PD(M) is a labelled directed graph over A, with labels from G or E, satisfying the following rules: (1) if an assertion R is related to another assertion S, by an unique *non-dotted* arrow labelled  $e \in E$  (where e does not model a fault), then the property  $R \leadsto S$  is satisfied; (2) if R is related to  $S_1, \ldots S_p$ , then each arrow from R to  $S_i$  is labelled by a guard  $g_i \in G$ . The diagram D possesses proved properties:

- 1. If M satisfies  $P \rightsquigarrow Q$  and  $Q \rightsquigarrow R$ , it satisfies  $P \rightsquigarrow R$ .
- 2. If M satisfies  $P \leadsto Q$  and  $R \leadsto Q$ , it satisfies  $(P \lor R) \leadsto Q$ .
- 3. If I is invariant for M and if M satisfies  $P \wedge I \rightsquigarrow Q$ , then M satisfies  $P \rightsquigarrow Q$ .
- 4. If *I* is invariant for *M* and if *M* satisfies  $P \wedge I \Rightarrow Q$ , then *M* satisfies  $P \rightsquigarrow Q$ .
- 5. If  $P \stackrel{e}{\longrightarrow} Q$  is a link of D for the machine M, then M satisfies  $P \rightsquigarrow Q$ .
- 6. If P and Q are two nodes of D such that there is a path in D from P to Q and any path from P can be extended in a path containing Q, then M satisfies  $P \rightsquigarrow Q$ .
- 7. If I, U, V, P, Q are assertions such that I is the invariant of M;  $P \land I \Rightarrow U$ ;  $V \Rightarrow Q$ ; and there is a path from U to V and each path from U leads to V; then M satisfies  $P \leadsto Q$ .

These *refinement diagrams* are attached to EVENT B models and are used for deriving liveness properties. As an example, the diagram in Fig.3 represents a model of a self-stabilizing system: the diagram relates a pair of assertions  $(\neg P, P)$ , where  $\neg P$  is a precondition stating that the studied system is in an *illegal* state (P does not hold); and P is the post-condition, describing the *desired legal* state. We observe that the *leads to* property  $(\neg P) \rightsquigarrow P$ , demonstrating the stabilization and convergence, is satisfied by the diagram and the model linked to it.

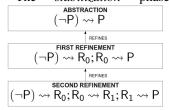

**Applying the** *Service-as-Event* **Paradigm** [3] We apply the *service-as-event* paradigm, for formalizing the self-\* systems.

1. **Describing** *stabilization* and *convergence* as a service. We express the *stabilization* and *convergence* properties of a self- $\star$  system  $\mathcal{S}$ , where service is stated by the following property:  $(\neg P) \leadsto P$ . An abstract event (e) is used for describing the service/procedure represented by  $(\neg P) \leadsto P$ :  $(\neg P) \stackrel{e}{\to} P$ ; where  $(\neg P)$  is a *pre-condition* for triggering event (e); and P is a *post-condition* defined by the actions of event (e), which should be satisfied by the "execution" of event.

2. **Decomposing** *stabilization* and *convergence* into simple steps. We decompose the abstract service stated by  $(\neg P) \leadsto P$  into simple *sub-procedures/steps*, using the *inference rules* [11] related to the *leads to* properties:

Fig. 4: Proof Tree - Usage of Inference Rules

This process is similar to refinement (see Fig.5), since we add, at each level of the proof tree, a new state  $R_k$  ( $0 \le k \le n$ ) leading from ( $\neg P$ ) to P. The initial property ( $\neg P$ )  $\leadsto P$  is decomposed, until the identification of the *stabilization* steps is satisfactory. The *stabilization* phase is expressed by the property

expressed by the property  $(\neg P) \rightsquigarrow R_0 \land R_0 \rightsquigarrow R_1 \land \dots \land R_{n-1} \rightsquigarrow R_n \land R_n \rightsquigarrow P$ , which states the *convergence* leading to the *desired legal* states. Each level of the proof tree corresponds to a level of refinement (see Fig.5) in the formal development. Each *leads to* property demonstrates a *service* of

Fig. 5: Decomposition and Refinement property demonstrates a *service* of *stabilization*, which is defined by an event in the model.

# 4 Stepwise Design of the Self-Healing Approach

#### 4.1 Introduction to the Self-Healing P2P-Based Approach

The development of self-healing P2P-based approach is proposed by Marquezan et al. [14], where system reliability is the main concern. The self-healing process ensures the maintenance of proper functioning of the system services. If a service fails then it switches from a *legal* state to a *faulty* state. The self-healing/recovery procedure ensures that the service switches back to the *legal* state. The services run in a distributed (P2P) system composed of agents/peers executing instances of tasks. The services and peers notions are introduced as: (1) Management Services: Tasks/Services are executed by the peers; (2) Instances of Management Services: Peers executing a certain type of management service; (3) Management Peer Group (MPG): Instances of the same management service. The self-healing property can be described as follows: (1) Self**identification** triggers to detect the failure of service. This mechanism identifies running or failed instances of a management service. (2) Self-activation is started, whenever a management service will be detected fail by the self-identification. Self-activation evaluates if the management service needs a recovery, based on the criticality of the failure: if there are still enough instances for running the service, the recovery procedure is not started; otherwise, the *self-configuration* mechanism is triggered for repairing the service. (3) Self-configuration is activated if the failure of service is critical: the role of this mechanism is to instantiate the failed management service, and to return the service into a legal state.

#### 4.2 The Formal Design

Figure 6 depicts the formal design of *self-healing P2P-based approach*. The model M0 abstracts the self-healing approach. The refinements M1, M2, M3 introduce step-by-step the *self-detection*, *self-activation* and *self-configuration* phases, respectively. The remaining refinements, from M4 to M20, are used for localisation of the system: each step of the algorithm is made *local* to a node. The last refinement M21 presents a local model that describes a set of procedures for recovering process of P2P system.

Fig. 6: Architecture

**Abstracting the Self-Healing Approach (M0)** This section presents an abstraction of the self-healing procedure for a failed service. Each service (s) is described by two states: RUN (legal/running state) and FAIL (illegal/faulty state). A variable serviceState is defined as  $s \mapsto st \in serviceState$ , where s denotes a service and st denotes a possible state. A property P expresses that a service (s) is in a  $legal\ running$  state that is formalised as  $P = (s \mapsto RUN \in serviceState)$ . An event FAIL-URE models a faulty behaviour, where service (s) enters into a faulty state (FAIL), satisfying  $\neg P$ . The self-healing of management service (s) is expressed as ( $\neg P$ )  $\rightsquigarrow P$ . The recovery procedure is stated by an event HEAL (( $\neg P$ )  $\xrightarrow{HEAL} P$ ), where service (s) recovers from an  $illegal\ faulty$  state (FAIL) to a  $legal\ running$  state (RUN). The refinement diagram (see Fig.7) and events sum up the abstraction of a recovery procedure.

\cup \{s \mapsto RUN\}
```

This *macro/abstract view* of the *self-healing* is detailed by refinement<sup>2</sup>, using intermediate steps. A set of new variables is introduced to capture the system requirements. The variables are denoted by  $NAME_{nement Level}$ .

**Introducing the Self-Detection (M1)** The variable *serviceState* is replaced, by refinement, with a new variable *serviceState*\_1, since new states are introduced. The states *RUN*, *FAIL* are refined into *RUN*\_1, *FAIL*\_1, and a new state (*FL\_DT*\_1) is defined. A service (*s*) can *suspect* and *identify* a failure state (*FAIL*\_1) before triggering the recovery (HEAL). We introduce a property  $R_0 = (s \mapsto FL\_DT\_1 \in serviceState\_1)$  and a new event FAIL\_DETECT in this *self-detection* mechanism. Let P and  $\neg$ P be redefined as follows:  $P = (s \mapsto FUN\_1 \in serviceState\_1)$  and  $\neg$ P  $= (s \mapsto FAIL\_1 \in serviceState\_1)$ .

<sup>&</sup>lt;sup>1</sup> The assertions ( $s \mapsto st \in serviceState$ ), describing the state (st) of a service (s), are shorten into (st), in the nodes of the refinement diagrams, for practical purposes.

 $<sup>^2</sup>$   $\oplus$ : to add elements to a model,  $\ominus$ : to remove elements from a model

The intermediate steps of self-detection are introduced according to the refinement diagram (see Fig.8) and proof tree.

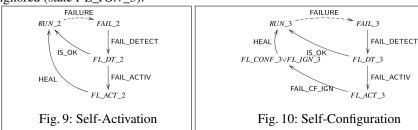

$$\frac{ (\neg P) \rightsquigarrow R_0 \qquad R_0 \rightsquigarrow P}{ (\neg P) \rightsquigarrow P} \textit{ trans}$$

The event FAIL\_DETECT is introduced to express the *self-detection*: the failure state ( $FAIL_1$ ) of a service (s) is detected (state  $FL_DT_1$ ).

The property  $(\neg P) \rightsquigarrow R_0$  is expressed by the event FAIL\_DETECT, where the failure  $(FAIL\_1)$  of service (s) is identified  $(FL\_DT\_1)$ .  $R_0 \rightsquigarrow P$  is defined by the event HEAL, where the service (s) is restored to a *legal running* state  $(RUN\_1)$  after failure detection. The same method is applied to identify all the phases of *self-healing* algorithm. Due to limited space, we focus on the interesting parts of models and liveness properties. The complete formal development of models can be downloaded from web<sup>3</sup>.

Introducing the Self-Activation (M2) and Self-Configuration (M3) The *self-activation* is introduced in this refinement M2 (see Fig. 9), where a failure of a service (s) is evaluated in terms of critical or non-critical using a new state  $FL\_ACT\_2$  and an event FAIL\_ACTIV. The *self-configuration* step is introduced in the next refinement M3 (see Fig. 10), which expresses that if the failure of service (s) is critical, then the *self-configuration* procedure for a service (s) will be triggered (state  $FL\_CONF\_3$ ), otherwise, the failure will be ignored (state  $FL\_IGN\_3$ ).

**The Global Behaviour (M4)** The developed models are refined and decomposed into several steps (see Fig.11) [14]. These steps are: (1) *Self-Detection*, (2) *Self-Activation*, and (3) *Self-Configuration*. Self-Detection phase is used to detect any failure in the autonomous system using two events FAIL\_DETECT and IS\_OK. The event FAIL\_DETECT models the failure detection; and the event IS\_OK states that if a detected failure of a service (s) is a *false alarm*, then the service (s) returns to a *legal* state (*RUN*\_4). Self-Activation process is used to evaluate when actual failures are identified, using

<sup>3</sup> http://eb2all.loria.fr/html\_files/files/selfhealing/self-healing.zip

the following events: FAIL\_ACTIV, FAIL\_IGN, IGNORE, and FAIL\_CONF. The events FAIL\_IGN and IGNORE are used to ignore the failure of service (s) when failure is not in critical state ( $FL_IGN_-4$ ). The event FAIL\_CONF is used to evaluate the failure of service (s) when failure is critical ( $FL_CONF_-4$ ). The last phase Self-Configuration presents the healing procedure of a *failed* service using an event REDEPLOY.

From model M5 to M20, we localise the events (we switch from a *service* point of view to the instances/peers point of view) and detail the macro (global) steps by

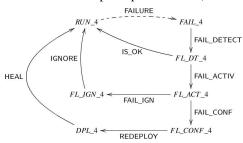

Fig. 11: Self-Healing steps

adding new events, variables, constraints. The refinements M5, M6, M7 introduce the running  $(run\_peers(s))$ , faulty  $(fail\_peers[\{s\}]),$ suspicious  $(susp\_peers(s))$ and deployed peers/instances  $(dep\_inst[\{s\}])$ for a service (s). A function (min inst) associates each service (s) with the minimal number of instances that is required

running service (*s*), and helps to detail the *self-activation* phase: if the number of running instances of service (*s*) is below than minimum, then the failure is critical. The models M8, M9, M10 detail the *self-detection* and *self-configuration* phases to introduce the *token owners* for the services. Models from M11 to M20 localise gradually the events (to switch from a *service* point of view to the instances/peers point of view). The detailed formal development of various steps from M5 to M20 are given in the archive <sup>3</sup>. Due to limited space, in the following section, we present only the local model M21.

**The Local Model (M21)** This model details locally the *self-healing* procedure of a service (s). The peers instantiating management service (s) are introduced, as well as the notion of token owner. The token owner is a peer instance of service (s) that is marked as a token owner for the Management Peer Group (MPG). It can perform the self-healing procedure using self-detection, self-activation, and self-configuration steps. (1) Self-Detection introduces an event SUSPECT\_INST that states that the token owner for service (s) is able to suspect a set (susp) of unavailable peers instances of service (s). Other events RECONTACT INST OK and RECONTACT INST KO are used to specify the successful recontact, and failed recontact, respectively, of the unavailable instances for ensuring the failed states. Moreover, the token owner is able to monitor the status of service (s) using two events FAIL DETECT, and IS OK. If there are unavailable instances after the recontacting procedure, the token owner informs the safe members of MPG of failed instances using the event FAIL DETECT, otherwise, the token owner indicates that service is running properly. (2) Self-Activation introduces an event FAIL ACTIV that states that if there are failed instances of service (s), then the token owner evaluates if the failure is critical. Another event FAIL IGNORE specifies that the failure is not critical. An event IGNORE can ignore the failure if several instances (more than minimum) are running correctly. If the number of instances for the running service (s) will be less than the minimum required services, then the failure will be declared critical, and the self-healing process will be triggered using an event FAIL CONFIGURE. (3) SelfConfiguration introduces three events REDEPLOY\_INSTC, REDEPLOY\_INSTS and REDEPLOY that specify that if the failure of service (*s*) is critical, then new instances of running service (*s*) can be deployed until to reach the minimal number of instances, and after the event HEAL can be triggered corresponding to the *convergence* of the self-healing process.

It is noticeable that the *architectural decomposition* of the self-healing process is emphasized in this model, by the events related to the algorithm. There is also a set of events describing actions related to the environment. MAKE\_PEER\_UNAVAIL: a set of

```

peers (*prs*) becomes unavailable (can not be contacted); MAKE\_PEER\_AVAIL: a formerly unavailable instance (*p*) becomes available; UNFAIL\_PEER: a failed instance re-enters a *legal running* state.

This model M21 describes locally the Self-Healing P2P-Based Approach, where we have formulated hypotheses for ensuring the correct functioning of the self-healing process: (1) Event MAKE\_PEER\_AVAIL: If the token owner of a service (s) becomes unavailable, at least one peer, with the same characteristics as the disabled token owner (state, local informations about running, failed peers, etc.) can become the new token

owner of service (s); (2) Event REDEPLOY\_INSTC: There is always a sufficient number of available peers that can be deployed to reach the legal running state of a service (s).

In a nutshell, we say that our methodology allows users to understand the self-\* mechanisms and to gain insight into their architectures (components, coordination, etc.); and gives evidences of the correctness of self-\* systems under some assumptions/hypotheses.

### 5 Analysis of Temporal Properties for Event-B Models

Leuschel et al. [13] developed a tool ProB for animating, model-checking, and verifying the consistency of Event-B models. ProB provides two ways for analysing Event-B models: constraint-based checking and temporal model-checking. We focus on temporal model-checking, since we are interested in liveness properties. Temporal model-checking [13] allows ProB to detect problems with a model (invariants violation, deadlocks, etc.) and to verify if the model satisfies LTL properties: ProB explores the state space of the model and tries to find a counter-example (i.e. a sequence of events) leading to the violation of invariants or LTL properties.

A difference with TLC (model-checker for TLA<sup>+</sup>) is that ProB does not support *fairness* [9], allowing unfair traces to be analysed during model-checking. Therefore, the TLA<sup>+</sup> framework is more suited to our work, since we are verifying liveness properties, in Event-B models, under fairness assumptions.

#### 6 Discussion, Conclusion and Future Work

We present a methodology based on liveness properties and *refinement diagrams* for modelling the self-\* systems using EVENT B. We characterize the self-\* systems by three modes (abstract states): 1) *legal (correct)* state, 2) *illegal (faulty)* state, and 3) *recovery* state. We have proposed a generic pattern for deriving correct self-\* systems (see Fig.1). The *service-as-event* and *call-as-event* paradigms provide a way to express the relationships between modes for ensuring required properties as convergence. The *correct-by-construction* principle gives us the possibility to refine procedures from events and to link modes. The key idea is to identify the modes (considered as abstract states) and the required abstract steps to allow the navigation between modes, and then to gradually enrich abstract models, using refinement to introduce the concrete states and events. We have illustrated our methodology by the *self-healing approach* [14].

The complexity of the development is measured by the number of proof obligations (PO) which are automatically/manually discharged (see Table 1). It should be noted that a large majority ( $\sim 70\%$ ) of the 1177 manual proofs is solved by simply running the provers. The actual summary of proof obligations is given by Table 2. The manually discharged POs (327) require analysis and skills: searching and adding premises, simplifying the complex predicates, and even transforming goals are needed to discharge these POs. Examples of difficult POs are related to proving the *finiteness* of *Management Peer Groups (MPG)*, during the *redeployment operation* of the *self-configuration phase*.

Furthermore, our refinement-based formalization allows us to produce final local models close to the *source code*. Our future works include the development of techniques for generating applications from the resulting model extending tools like EB2ALL [16]. Moreover, further case studies will help us to discover new patterns;

these patterns will be added to a catalogue of patterns that could be implemented in the Rodin platform. Finally, another point would be to take into account dependability properties in our methodology.
