## ABSTRACT

This paper describes a generalization of the god-object method for haptic interaction between rigid bodies. Our approach separates the computation of the motion of the six degree-of-freedom god-object from the computation of the force applied to the user. The motion of the god-object is computed using continuous collision detection and constraint-based quasi-statics, which enables high-quality haptic interaction between contacting rigid bodies. The force applied to the user is computed using a novel constraint-based quasi-static approach, which allows us to suppress force artifacts typically found in previous methods. Our approach has been implemented on a 3.2 GHz Xeon bi-processor and has been successfully tested on complex benchmarks. Our results show that the separation into asynchronous processes allows us to satisfy the different update rates required by the haptic and the visual displays. The constraint-based force applied to the user, which handles any number of simultaneous contact points, is typically computed within a few microseconds, while the update of the configuration of the rigid god-object is performed within a few milliseconds for rigid bodies containing up to tens of thousands of triangles.

**Keywords:** Haptics, God-Object, Six degrees of freedom, Rigid bodies, Constraint-based quasi-statics

## 1 INTRODUCTION

Haptic display of rigid bodies has the potential to improve the interaction between a human and a virtual environment by providing the user with the ability to touch and feel the geometric details of the virtual objects. Typical applications include CAD/CAM design, virtual prototyping, scientific visualization and medical simulation.

Because of the high computational requirements of haptic rendering, however, finding effective methods is still a great challenge. A classical three degree-of-freedom method for haptic display of the interaction of a point and a virtual object was introduced by Zilles and Salisbury [30]. The two main benefits of their approach are (a) a non-penetrating simulation of the motion of the point as it slides on the surface of the obstacles; (b) a constraint-based computation of the force applied to the user, which results in a force orthogonal to the constraints. These features are highly desirable, in that non-interpenetration of virtual objects is known to increase their perceived stiffness [26], and that an incorrect orientation of the force has been shown to perturb the perceived orientation of the virtual surfaces [24].

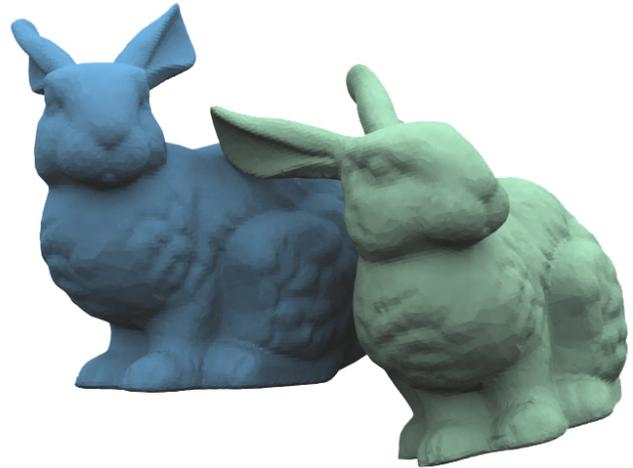

Figure 1: **Haptic interaction with Stanford Bunnies.** The approach described in this paper allows us to provide a user with high-quality haptic display of contacting rigid bodies (here, two Stanford bunnies containing about 27,000 triangles each). Our constraint-based force computation method allows the manipulated object to come in contact with and slide on the environment obstacles without penetrating them, while providing the user with precise haptic display, where each vertex, edge and face can potentially be felt.

Although several six degree-of-freedom haptic rendering methods have been proposed (*cf* Section 2), none seems to preserve all of the properties of the initial three degree-of-freedom approach introduced by Zilles and Salisbury [30]: these methods might allow the virtual objects to interpenetrate, or they use some form of virtual coupling [5] which can lead to disturbing force artifacts, by modifying the orientation of the force applied to the user. In this paper, we propose what seems to be the first six degree-of-freedom constraint-based method that prevents both these visual and haptic artifacts. Especially, we make the following contributions:

- **Six degree-of-freedom god-object method:** we extend the three degree-of-freedom god-object method proposed by Zilles and Salisbury [30] to six degree-of-freedom haptic interaction between rigid bodies.
- **High-quality god-object simulation:** our god-object simulation method prevents any interpenetration between the virtual objects, while allowing the god-object to precisely contact and slide on the surface of the obstacles. This results in highly detailed haptic rendering of the objects geometries, and increases the perceived stiffness of the virtual objects [26].
- **Constraint-based force computation:** we introduce a novel constraint-based quasi-static approach to compute the motion of the god-object and the force applied to the user. The

constraint-based approach is physically-based, handles any number of simultaneous contact points, and yields constraint forces that are orthogonal to the constraints, thereby rendering correct surface orientations to the user.

- **Dissipative quasi-statics:** we show that our constraint-based quasi-static approach can only dissipate the energy transmitted to the god-object. This helps us improve the stability of the haptic display.

The paper is organized as follows. Section 2 provides a summary of related work. Section 3 gives an overview of our approach. Section 4 describes how we compute the motion of the god-object to ensure realistic haptic interaction with rigid bodies. Section 5 presents our novel constraint-based quasi-static approach to computing the force applied to the user. Section 6 demonstrates our approach on several benchmarks and shows how our approach is able to provide the user with high-quality haptic display of contacting rigid bodies. We also discuss the benefits and limitations of our approach. Finally, Section 7 concludes and details several future research directions.

## 2 RELATED WORK

Haptic display of virtual objects has been an active area of research over the last decade. In 1995, Zilles and Salisbury [30] proposed what appears to be the first constraint-based method for three degree-of-freedom haptic rendering of generic polygonal objects. They introduced the *god-object*, an idealized representation of the position of the haptic device that is constrained on the surface of the obstacles. At each time step, the location of the god-object minimizes the distance to the haptic device, and the difference between the two positions provides the force direction. Ruspini *et al.* [23] extends this approach by replacing the god-object by a small sphere, and proposes methods to smooth the object surface and add friction. Several authors have proposed to extend the virtual proxy approach to three degree-of-freedom interaction with objects defined by implicit representations [25, 13].

Some authors have proposed six degree-of-freedom haptic display algorithms. McNeely *et al.* [18] proposed a voxel sampling method. Johnson and Willemsen [12] use local minimum distances to compute the force applied to the user. Gregory *et al.* [8] extend the virtual proxy approach to six degrees of freedom and estimate the local penetration depth to compute the force and torque applied to the user. These methods, like most six degree-of-freedom haptic display methods [15, 19, 9, 6], do not attempt to prevent the interpenetration between the virtual objects, which might lead to miss some collisions between the virtual objects and can lead to the well-known *pop-through effect*, where the virtual proxy can traverse thin objects or objects parts [23], thereby degrading the perception of geometric details. Berkelman *et al.* [4] have proposed a general constraint-based method for six degree-of-freedom interaction with rigid bodies. However, their approach includes a virtual coupling [5] which leads to perceptible force artifacts (*cf* discussion in Section 6). Recent work on stable six degree-of-freedom interaction by Otaduy and Lin [20], however, has shown that the force artifacts created by a virtual coupling can be reduced through the use of an implicit integration method.

To the best of our knowledge, the approach described in this paper seems to be the first six degree-of-freedom constraint-based haptic rendering method that does not suffer from the visual or haptic artifacts of previous approaches (*i.e.* interpenetrations, forces felt at a distance, or artificial friction and sticking).

## 3 OVERVIEW

Our method extends the classical three degree-of-freedom constraint-based method by Zilles and Salisbury [30] by employing a *six degree-of-freedom god-object*, *i.e.* an idealized representation

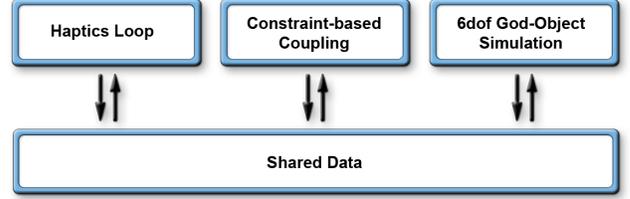

Figure 2: **Schematic representation of our method.** Our method for haptic display of six degree-of-freedom manipulation of rigid bodies is divided in three asynchronous blocks (*cf* Section 3).

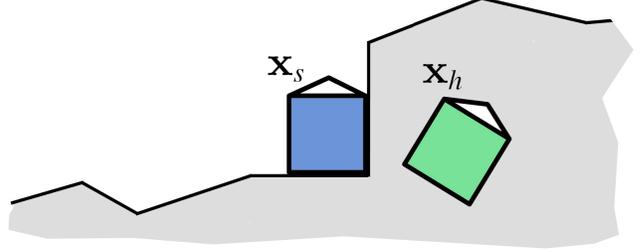

Figure 3: **Six degree-of-freedom god-object.** Although the haptic device penetrates the environment obstacles (configuration  $x_h$ ), the god-object is constrained to remain on the surface of the obstacles (configuration  $x_s$ ). We propose new algorithms to compute the motion of the god-object and the force applied to the user based on the discrepancy between these two configurations.

of the haptic device that is constrained to remain on the surface of the environment obstacles when the haptic device penetrates the environment obstacles (*cf* Figure 3). Only the god-object is displayed (and not the actual configuration of the haptic device), so that even when the haptic device penetrates the environment obstacles, the user only sees the rigid body that he manipulates in a realistic, contacting only configuration. As a result, the user feels that the rigid body he or she is manipulating is correctly sliding on the surface of the obstacles. The motion of the god-object and the force applied to the user are computed from the discrepancy between the configurations of the god-object and the haptic device, thanks to a novel constraint-based quasi-static approach which suppresses visual and haptic artifacts typically found in previous approaches.

Our algorithm is divided in three asynchronous loops: (a) the god-object simulation loop, which updates the configuration of the god-object based on the configuration of the haptic device and the environment obstacles; (b) the constraint-based coupling loop, which determines the constraint-based force applied to the user based on the configurations of the god-object and the haptic device, as well as the current set of contact points and normals; (c) the haptics loop, which controls an impedance-like haptic device which reads the force that has to be applied to the user and writes the current configuration of the haptic device (*cf* Figure 2). The haptics loop is considered as a generic black box, and this paper focuses on the two other processes, *i.e.* the god-object simulation loop and the constraint-based coupling loop.

## 4 SIX DEGREE-OF-FREEDOM GOD-OBJECT SIMULATION

### 4.1 Overview

The motion of the god-object is computed based on the relative configurations of the haptic device and the god-object, as well as the current set of contact points. Precisely, we perform a constraint-based quasi-static simulation of the god-object according to the following *god-object simulation algorithm*:

1. **Data retrieval:** The six-dimensional configuration  $x_h$  of the haptic device is retrieved from the shared data (*cf* Figure 2).

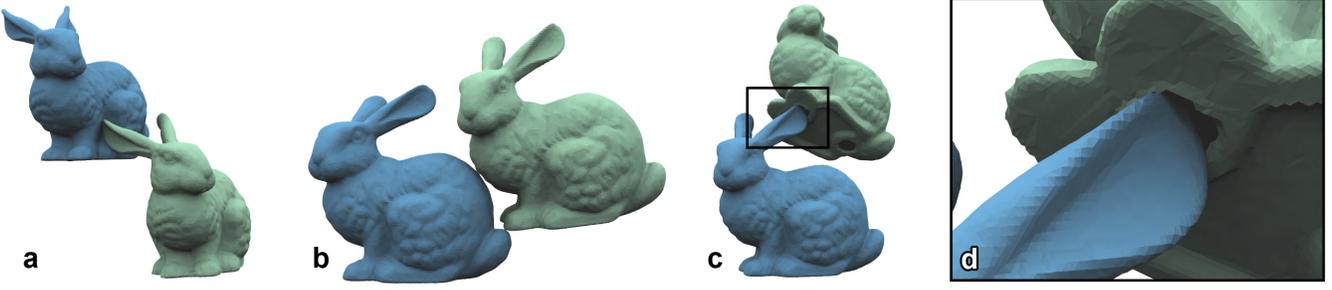

Figure 4: **Haptic interaction with Stanford Bunnies.** The user manipulates the green bunny. **a:** the ear of the green bunny slides in a ridge of the blue bunny. **b:** continuous collision detection and constraint-based quasi-statics allows the manipulated object to precisely contact and slide on the obstacles. **c-d:** our method provides the user with the ability to precisely feel the contact between pairs of triangles, resulting in highly detailed haptic display of contacting rigid bodies.

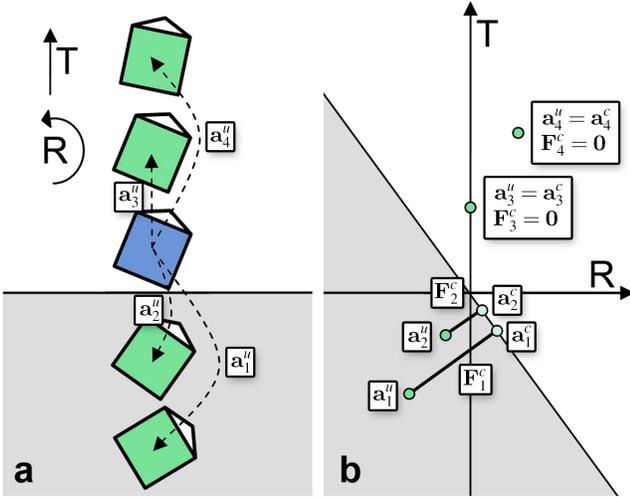

Figure 5: **Constraint-based force computation.** Our method uses Gauss' least constraints principle to compute the constrained motion of the god-object and the constraint-based force applied to the user (cf Sections 4 and 5).

- Unconstrained acceleration computation:** The unconstrained six-dimensional acceleration  $\mathbf{a}^u$  of the god-object is computed from  $\mathbf{x}_h$  and the six-dimensional configuration  $\mathbf{x}_s$  of the god-object:

$$\mathbf{a}^u = k_s(\mathbf{x}_h - \mathbf{x}_s),$$

where  $k_s$  is a coupling constant ( $k_s = 0.5$  in our implementation). This is similar to the virtual coupling method [5], except that we directly control the acceleration of the god-object. Because the motion of the god-object is quasi-static, this amounts to directly control the displacement of the god-object.

- Constraint-based quasi-static computations:** The constrained acceleration  $\mathbf{a}^c$  of the god-object is computed based on the current contact information (*i.e.* the one resulting from the previous god-object simulation step) and the unconstrained acceleration  $\mathbf{a}^u$ . This involves forming the  $6 \times 6$  god-object mass matrix  $\mathbf{M}$  and the  $6 \times m$  contact Jacobian  $\mathbf{J}$ , where  $m$  is the number of contact points (cf details below).

- Collision detection:** The *target configuration* of the god-object is computed from its constrained acceleration using an explicit Euler integration step. We use the continuous collision detection algorithm introduced by Redon *et al.* [21] to detect collisions on a path interpolating the current and

target god-object configurations. If the interpolating path is free of collisions, the god-object is placed in the target configuration. If a new contact occurs, however, the continuous collision detection algorithm determines the first contacting configuration along the interpolating path, as well as the new contact positions and normals. The configuration reached by the god-object at the end of this step is the *new god-object configuration*.

- Constraints transmission:** The matrices  $\mathbf{M}$  and  $\mathbf{J}$  corresponding to the new god-object configuration are written to the shared data, so that they can be retrieved by the constraint-based coupling loop to compute the constraint-based force applied to the user.

The god-object simulation loop ensures that the god-object attempts to reach the same position and orientation as the haptic device. Continuous collision detection and constraint-based quasi-statics allow the god-object to slide on virtual obstacles without penetrating them as it tries to reach the haptic device. In the following, we describe how we derive the constraint-based quasi-statics of the god-object using Gauss' least constraint principle.

## 4.2 Constraint-based God-Object Quasi-Statics

Let  $\mathbf{a} = (\mathbf{a}_G, \alpha)^T$  denote the generalized (six-dimensional) acceleration of the god-object, where  $\mathbf{a}_G$  and  $\alpha$  are respectively the linear acceleration and the angular acceleration of the god-object. The set of *possible* accelerations is easily determined from the contact positions and normals provided by the continuous collision detection algorithms. Let  $I_k$  and  $\mathbf{n}_k$  respectively denote the position and normal of the  $k$ -th contact point,  $1 \leq k \leq m$ . Assuming the normal  $\mathbf{n}_k$  is directed towards the exterior of the environment obstacle, the acceleration of the god-object must satisfy the following *non-penetration constraint* [2]:  $\mathbf{a}_G^T \mathbf{n}_k + \alpha^T (GI_k \times \mathbf{n}_k) \geq 0$ , where  $GI_k$  is the vector from the center of inertia  $G$  of the god-object to the contact point  $I_k$ . Note the absence of velocity-dependent term in the non-penetration constraint, as the quasi-static assumption implies that the velocity of the god-object is zero at all times. These  $m$  non-penetration constraints can be concatenated to form a single constraint on the generalized acceleration of the god-object:  $\mathbf{J}\mathbf{a} \geq \mathbf{0}$ , where  $\mathbf{J}$  is a  $m \times 6$  *Jacobian*.

Gauss' principle states that the constrained generalized acceleration  $\mathbf{a}^c = (\mathbf{a}_G^c, \alpha^c)^T$  of the god-object minimizes the following function [7]:

$$\mathcal{G}(\mathbf{a}) = \frac{1}{2}(\mathbf{a} - \mathbf{a}^u)^T \mathbf{M}(\mathbf{a} - \mathbf{a}^u) = \frac{1}{2} \|\mathbf{a} - \mathbf{a}^u\|_{\mathbf{M}}^2, \quad (1)$$

that is, the *kinetic distance*  $\|\mathbf{a}^c - \mathbf{a}^u\|_{\mathbf{M}}$  between the constrained acceleration  $\mathbf{a}^c$  and the unconstrained acceleration  $\mathbf{a}^u$ , over the set

of possible accelerations  $\{\mathbf{a} : \mathbf{J}\mathbf{a} \geq \mathbf{0}\}$ . In other words, the constrained acceleration  $\mathbf{a}^c$  is the (non-euclidean) projection of the unconstrained acceleration  $\mathbf{a}^u$  onto the set of possible accelerations. This projection problem is solved using Wilhelmsen’s projection algorithm [29]. Note that the matrices  $\mathbf{M}$  and  $\mathbf{J}$  contain all the necessary and sufficient information to compute the constrained motion of the god-object.

## 5 CONSTRAINT-BASED FORCE COMPUTATION

The constraint-based coupling loop determines the forces applied to the user based on the position of the haptic device and the contact information sent by the god-object simulation loop. Essentially, the constraint-based coupling loop performs the same constraint-based quasi-static computations as in the god-object simulation loop, but *assuming the position and orientation of the god-object is fixed*. This suppresses the need for collision detection in the constraint-based coupling loop, and allows us to compute the constraint-based force applied to the user within a few *microseconds* (cf Section 6). Precisely, the constraint-based force applied to the user is computed according to the following *constraint-based force computation algorithm*:

1. **Data retrieval:** The configuration  $\mathbf{x}_h$  of the haptic device and the configuration  $\mathbf{x}_s$  of the god-object are read from the shared data, as well as the matrices  $\mathbf{M}$  and  $\mathbf{J}$ , computed in the god-object simulation loop, which describe the local quasi-statics of the god-object.
2. **Unconstrained acceleration computation:** As in the god-object simulation loop, the unconstrained six-dimensional acceleration  $\mathbf{a}^u$  of the god-object is computed from  $\mathbf{x}_h$  and the six-dimensional configuration  $\mathbf{x}_s$  of the god-object ( $\mathbf{a}^u = k_s(\mathbf{x}_h - \mathbf{x}_s)$ ).
3. **Constraint-based force computation:** The constrained acceleration  $\mathbf{a}^c$  of the god-object is computed from the unconstrained acceleration  $\mathbf{a}^u$  and the matrices  $\mathbf{M}$  and  $\mathbf{J}$  retrieved from the shared data, by solving Gauss’ projection problem. The constraint-based force to be applied to the user is then  $\mathbf{F}^c = k_h \mathbf{M}(\mathbf{a}^c - \mathbf{a}^u)$ , where  $k_h$  is a coupling constant<sup>1</sup>.
4. **Force transmission:** The constraint-based force  $\mathbf{F}^c$  is written to the shared data. It will be read by the haptic loop, for application to the user.

Figure 5 demonstrates this algorithm in the case of a god-object in contact with an obstacle. For clarity, only two degrees of freedom are allowed: a vertical translation and a rotation whose axis is orthogonal to the plane of the figure. Figure 5.a shows the god-object contacting the obstacle (in blue), and four successive configurations of the haptic device (in green), as well as the resulting unconstrained accelerations  $\mathbf{a}_1^u, \dots, \mathbf{a}_4^u$ . Figure 5.b shows the corresponding two-dimensional *motion-space*, *i.e.* the space of accelerations, and the linearized non-penetration constraint resulting from the contact point (the diagonal line). The possible accelerations are above this diagonal line. Projecting the unconstrained accelerations  $\mathbf{a}_1^u, \dots, \mathbf{a}_4^u$  on the set of possible accelerations yields the constrained accelerations  $\mathbf{a}_1^c, \dots, \mathbf{a}_4^c$ , as well as the corresponding constraint forces  $\mathbf{F}_1^c, \dots, \mathbf{F}_4^c$  applied to the user. Haptic configurations 1 and 2 result in a force and a torque which attempt to bring the haptic device back to a position reachable by the god-object, while haptic configurations 3 and 4, which correspond to accelerations satisfying the non-penetration constraint, do not generate any force.

<sup>1</sup>Different constants can be used for the translational and rotational parts, but this might lead to constraint forces that are not orthogonal to the non-penetration constraints (cf Section 6).

Note that, because the configuration  $\mathbf{x}_s$  of the god-object is not updated in the constraint-based coupling loop, the matrices  $\mathbf{M}$  and  $\mathbf{J}$  do not have to be updated either<sup>2</sup>. Hence, only the configuration of the haptic device changes, and the main computation involved is the determination of the constrained acceleration  $\mathbf{a}^c$ , which can be performed very efficiently (cf Section 6).

When a new set of constraints is available, some of the new non-penetration constraints might not be satisfied by the current configuration of the haptic device (cf Figure 6.a). This might create a large constraint force if the user has largely penetrated those new constraints. In order to smooth the constraint-based force applied to the user and reduce potentially large forces created by delays in the update of the set of constraints, we generalize the method introduced by Mark *et al.* [16]. Assume a new constraint  $\mathbf{J}_k \mathbf{a} \geq 0$  on the acceleration  $\mathbf{a}$  of the god-object occurs, where  $\mathbf{J}_k$  is a six-dimensional row vector (a row of the Jacobian). Assume that this constraint is not satisfied at time 0, when the new set of constraints becomes available, *i.e.* that the configuration of the haptic device is such that  $\mathbf{J}_k \mathbf{a}^u = d_k < 0$ . We initially *offset* this constraint: the constraint becomes  $\mathbf{J}_k \mathbf{a}^u \geq f_k(t)$ , where  $f_k$  is a monotonously increasing time-dependent function such that  $f_k(0) = d_k$  and  $f_k(\Delta t) = 0$ . This constraint is thus satisfied when the set of constraints is updated, and progressively turns into the constraint that should be enforced (*i.e.* after a time  $\Delta t$ , cf Figure 6.b-d). In order to provide the user with a slight force discontinuity and improve the perception of new constraints, however, we perform this interpolation only if  $d_k \leq \varepsilon$ , where  $\varepsilon$  acts as a user-defined discontinuity threshold ( $\varepsilon < 0$ ).

The combination of the god-object simulation loop and the constraint-based coupling loop results in the perception of six degree-of-freedom constraint forces as the user manipulates the virtual object and slides on the virtual obstacles.

## 6 RESULTS AND DISCUSSION

The validation of our approach is performed on a Stringed Haptic Workbench in which the SPIDAR-G, a tension-based six degree-of-freedom force-feedback device [14], allows a user to interact intuitively on a large two-screen display [27]. The entire algorithm is executed on a 3.2 GHz bi-processor Xeon PC, to which the haptic device is connected. This PC communicates with a cluster of PCs only dedicated to the stereo display on both screens of the Stringed Haptic Workbench. The communication between the Xeon PC and the cluster of PCs is ensured by UDP protocols.

Each of the three main loops is launched in its separate thread. The haptic device thread frequency is fixed by the device: the constraint-based force computed by the constraint-based coupling loop is read from the shared data and applied to the user at 1000 Hz. The frequencies of the constraint-based coupling thread and the god-object simulation thread vary over time, depending on the complexity of the models and the task being performed (cf below).

### 6.1 Peg-in-a-hole Benchmark

We first evaluate the quality and the stability of the haptic interaction in a simple but classical case: the peg-in-a-hole benchmark (cf Figure 7). This benchmark is well-known because, although it involves only very simple geometry (here, 288 triangles for the peg and 280 triangles for the box), it has typically been a challenge to provide a stable and realistic haptic display of the insertion of the peg, due to the multiple and potentially redundant contact points occurring during the task [8].

<sup>2</sup>In our implementation, a flag is used to signal the arrival of a new set of constraints to the constraint-based coupling loop. This flag, written to the shared data by the god-object simulation loop, allows us to avoid re-reading the matrices  $\mathbf{M}$ ,  $\mathbf{J}$ , and the god-object configuration  $\mathbf{x}_s$ , which further speeds up the constraint-based coupling loop.

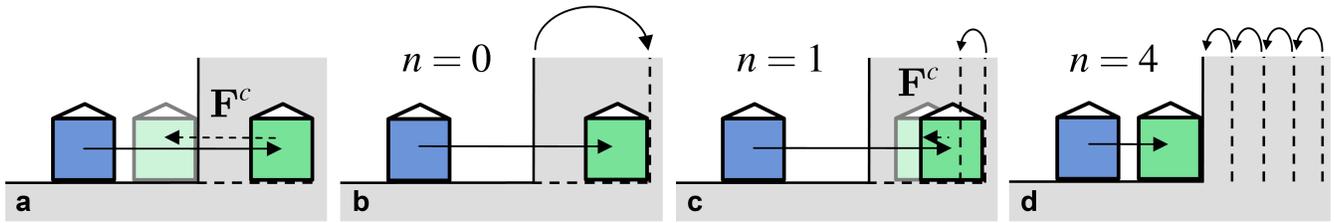

Figure 6: **Constraints adaptation.** When a new constraint (here a vertical plane) appears that would create too large a constraint force, it is first translated so that the constraint is satisfied by the current haptic device configuration, then progressively returned to its initial position. This helps us smooth the force felt by the user, while ensuring that small discontinuities signaling new contact points are felt.

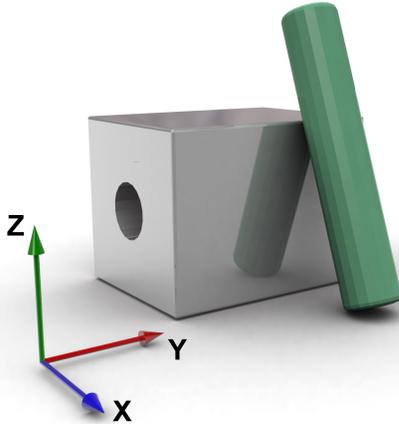

Figure 7: **The models used in the peg-in-a-hole benchmark.** The peg contains 288 triangles, while the hole contains 280 triangles. The hole is aligned with the Y axis.

Figure 8 reports several timings and statistics measured during a typical interaction. The first row reports several key configurations tested during the interaction, including (a) sliding the tip of the peg on the top side of the box, (b) laying the peg on the top side of the box and sliding it on the box, (c) pushing on the left side of the box, (d) exploring the right extremity of the hole and (e) inserting the peg in the hole. The second row reports the time required to compute the constraint-based force (*cf* Section 5) during the interaction. It can be seen that the constraint-based force is computed in less than 25 *microseconds* throughout the manipulation. The third row shows that the time required to update the configuration of the god-object is always smaller than 10 milliseconds, which is sufficient to prevent any visual lag throughout the manipulation. The fourth row reports the Y component of the constraint-based force applied to the user during the interaction. As expected, this component is non-zero only when the user pushes the peg on the left side of the box or explores the right extremity of the hole (steps (c) and (d)), and remains equal to zero whenever the peg is sliding on the top side of the box or inside the hole. In other words, the user does not feel any artificial friction force or any artificial sticking during the manipulation (*e.g.* the Y component of the force is never positive during step (c)). Finally, the fifth row reports the number of simultaneous contact points during the interaction, which can be seen to be fairly limited throughout the manipulation. This can be easily explained by the fact that (a) new contact points rarely occur exactly simultaneously, and (b) constraint-based quasi-static computations tend to limit the apparition of new contact points, since at most twelve of them can be independent. This greatly contributes to the efficiency of the constraint-based coupling loop.

Overall, the combination of continuous collision detection, constraint-based quasi-statics, and constraint-based force computation makes it very easy for the user to accomplish the task, by allowing the peg to slide on the surface of the box and the hole, while providing the user with a high-quality haptic display.

## 6.2 Stanford Bunnies Benchmark

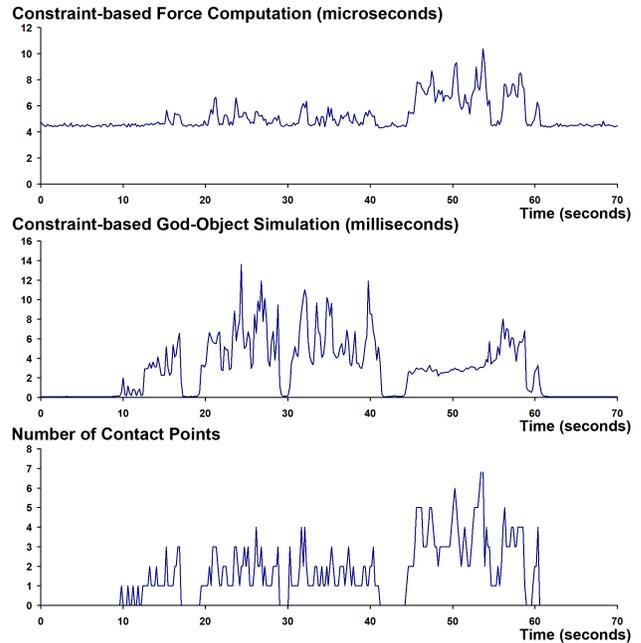

Figure 9: **Performance of our approach in the Stanford Bunny benchmark.** Even in this complex benchmark (27,000 triangles per bunny), our method is able to compute a constraint-based force within a few microseconds. The simulation of the god-object, which includes collision detection and constraint-based quasi-statics computations, is performed in less than 15 milliseconds, which is sufficient to prevent visual lag during the interaction.

The second benchmark involves two Stanford bunnies (27,000 triangles per bunny, *cf* Figure 1). One bunny is static, and the second bunny is manipulated by the user. Figure 4 shows several key steps of the interaction: Fig. 4.a shows the ear of the mobile bunny sliding in a ridge of the static bunny; Fig. 4.b demonstrates how the constraint-based god-object simulation provides realistic contacting configurations during the interaction; similarly, Fig. 4.c-d show how our approach is able to provide the user with high-quality haptic display of contacting rigid bodies, where the details of the geometry can be felt by the user.

Figure 9 reports on the performance of our approach during a typical interaction session with the bunnies, which includes the configurations represented in Figure 4. Again, the force applied to the user is computed within a few microseconds, while an update of the configuration of the mobile bunny, which includes continuous collision detection and constraint-based quasi-statics, is performed within a few milliseconds, resulting in the absence of any visual lag during the interaction.

## 6.3 Discussion

### 6.3.1 Benefits

The main benefits of our approach stem from the combination of three key elements:

- **Continuous collision detection** allows the user to feel the details of the geometry of the rigid bodies, and potentially feel the contact between vertices, edges and faces of the contacting objects. Furthermore, the ability to produce visually convincing non-penetrating but tangent contacting configurations (e.g. Fig. 4.b) helps us improve the perceived stiffness of the objects [26].
- **Asynchronous updates** of the configuration of the god-object and the force applied to the user help us satisfy the different update rates required by the haptic and the visual displays.
- **Constraint-based quasi-statics** allows the user to slide on the environment obstacles, and haptically feel the reduced motion sub-space resulting from the simultaneous non-penetration constraints, thus providing the user with a realistic haptic display of surfaces, corners, ridges, and object/object contact in general.

Especially, the physically-based computation of the force applied to the user guarantees that no *artificial friction or sticking is felt*, and that no force is applied when the god-object is in free space. This is to be contrasted to what would occur if some kind of virtual coupling was involved in the computation of the force applied to the user. Figure 10 shows such a comparison, in which the god-object (in blue) is constrained to remain above the surface of the obstacle. In the case depicted in Fig. 10.a, where the haptic device (in green) has penetrated the environment, a virtual coupling would attempt to bring the haptic device back to the position of the god-object, which would result in an artificial tangential friction applied to the user. As mentioned before, this would degrade the perceived orientation of the surface of the obstacle [24]. In contrast, the constraint-based approach guarantees that the perceived orientation is correct, since the contact forces are always orthogonal to the constraints<sup>3</sup>. Furthermore, in the case depicted in Fig. 10.b, where the user moves away from the obstacle, a virtual coupling would attempt to bring the god-object back to the surface of the obstacle, which would result in a sticky feeling. In this case, however, the constraint-based approach yields the correct force ( $\mathbf{F}^c = \mathbf{0}$ ), since moving away from the obstacle surface satisfies the non-penetration constraint (hence,  $\mathbf{a}^c = \mathbf{a}^u$ ).

Finally, although a complete stability analysis is outside the scope of this paper and left as future work, we believe that the asynchronous constraint-based approach helps us improve the stability of the interaction. Indeed, it can be shown that the simulation of the god-object is purely dissipative, i.e. that the force  $\mathbf{F}^u = \mathbf{M}\mathbf{a}^u$  applied to the god-object is such that

$$(\mathbf{F}^u)^T \mathbf{a}^c \leq (\mathbf{F}^u)^T \mathbf{a}^u.$$

Thus, the non-penetration constraints can only dissipate the energy transmitted to the god-object<sup>4</sup>. Our tests have shown that the user

<sup>3</sup>Since the constrained acceleration of the god-object  $\mathbf{a}^c$  minimizes the kinetic distance  $\|\mathbf{a}^c - \mathbf{a}^u\|_{\mathbf{M}}$  to the unconstrained acceleration  $\mathbf{a}^u$  among the possible accelerations, it is such that  $(\mathbf{a}^c - \mathbf{a}^u)^T \mathbf{M}\mathbf{a}^c = 0$ , which implies that  $(\mathbf{F}^c)^T \mathbf{a}^c = 0$ .

<sup>4</sup>The proof is straightforward. Indeed,  $(\mathbf{F}^u)^T (\mathbf{a}^c - \mathbf{a}^u) = (\mathbf{a}^u)^T \mathbf{M}(\mathbf{a}^c - \mathbf{a}^u) = -\|\mathbf{a}^c - \mathbf{a}^u\|_{\mathbf{M}}^2 + (\mathbf{a}^c)^T \mathbf{M}(\mathbf{a}^c - \mathbf{a}^u)$ . Since  $(\mathbf{a}^c - \mathbf{a}^u)^T \mathbf{M}\mathbf{a}^c = 0$  (cf footnote 3),  $(\mathbf{F}^u)^T \mathbf{a}^c \leq (\mathbf{F}^u)^T \mathbf{a}^u$ . Note that we use the product of the force and the acceleration because we deal with the quasi-static case. This is the equivalent of the product of the force and the velocity used in typical analyses.

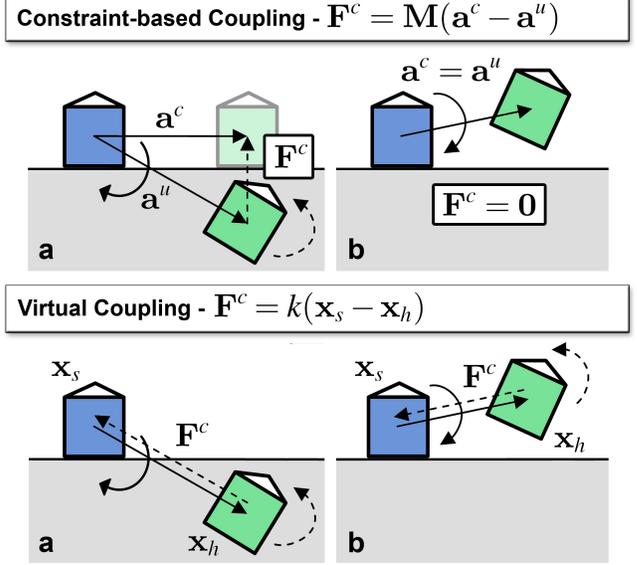

Figure 10: **Benefits of the constraint-based approach.** The constraint-based approach introduced in this paper allows us to remove force artifacts typically found in previous methods (cf Section 6).

is able to e.g. release the handle of the haptic device while the peg is inside the hole (Figure 8, step (e)).

### 6.3.2 Limitations

Our approach has two main limitations:

- **Linearized constraints:** in order to efficiently compute the quasi-statics of the god-object and the constraint-based force applied to the user, the non-penetration constraints are linearized. This might reduce the quality of the force applied to the user when a large discrepancy between the configurations of the god-object and the haptic device occurs. It would be interesting to investigate some more sophisticated force computation methods to address this problem, involving for example an implicit formulation of the non-penetration constraints.
- **Potentially low update rate of the set of constraints:** we do not guarantee that our approach is able to update the set of non-penetration constraints at 1000 Hz. This might lead to miss some high-frequency details when the user slides rapidly on the surface of the environment obstacles.

The potentially low update rate of the set of constraints is the main reason for the separation of the god-object simulation and the constraint-based force computation into asynchronous processes, in our approach and several previous ones (e.g. [6, 16]). Because the complexity of any collision detection method which reports all the contacting features is output-dependent, however, it seems arguable that, whichever collision detection method is used, it will always be possible to find a scenario such that the time required to determine all the contact points will take more than one millisecond. We have thus preferred to rely on a god-object simulation method which offers precise interaction with rigid bodies and, especially, precisely contacting configurations. Although this might limit the rate at which the set of non-penetration constraints is updated (sometimes as low as 70 Hz in the Stanford bunnies benchmark, and about 300 Hz on average), this approach allows us to compute a constraint-based force consistent with the current set of simultaneous constraints at extremely high rates (always higher than 80,000

Hz in the Stanford bunnies benchmark). Furthermore, it should be emphasized that the constraint-based computations performed in the constraint-based coupling loop *implicitly include some collision detection*. Returning to the example depicted in Figure 5, it can be seen that if, between two updates of the set of non-penetration constraints, the haptic device switches from a state where all currently known non-penetrating constraints are satisfied (in which case  $\mathbf{F}^c = \mathbf{0}$ ) to one where at least one of the currently known non-penetrating constraint is not satisfied (in which case  $\mathbf{F}^c \neq \mathbf{0}$ ), the user will feel this collision. In summary, collision detection is implicitly performed in the constraint-based coupling loop, for the current set of non-penetration constraints, at extremely high rates.

## 7 CONCLUSION AND FUTURE WORK

This paper has introduced a new method for six degree-of-freedom haptic display of rigid bodies, which generalizes the classical three degree-of-freedom god-object method introduced by Zilles and Salisbury [30]. As in their initial approach, the god-object is able to contact and slide on the environment obstacles without penetrating them, and the forces applied to the user are orthogonal to the non-penetration constraints. Our approach has been successfully tested on the classically difficult peg-in-a-hole benchmark and on some more complex models - two Stanford bunnies with 27,000 triangles each. We have shown that our method is able to provide a high-quality haptic display of contacting rigid bodies in both cases.

There are several directions for future work. Besides addressing the limitations described above, we would like to extend our approach to multiple dynamic objects (although it can be argued that quasi-static interaction is preferable for the simulation of many tasks, as few manipulation tasks seem to require using the inertia of the manipulated object to accomplish the task). As for enriching the haptic display, we note that some methods compute friction forces and simulate high-frequency textures based on the contact normals. Such approaches are perfectly compatible with our method and can be readily integrated. For example, force shading as proposed by Ruspini *et al.* [23] to smooth rigid bodies can be integrated by modifying the directions of the contact normals. In this case, as well, our constraint-based approach will ensure that no force artifacts will be felt by the user. Finally, we plan to investigate actual industrial scenarios such as virtual prototyping and assembly tasks.

## Acknowledgments

The authors wish to thank Dr. Ming C. Lin and Dr. Miguel A. Otaduy for insightful discussions, and Stanford University for the original bunny models.

### Peg-in-a-hole Benchmark

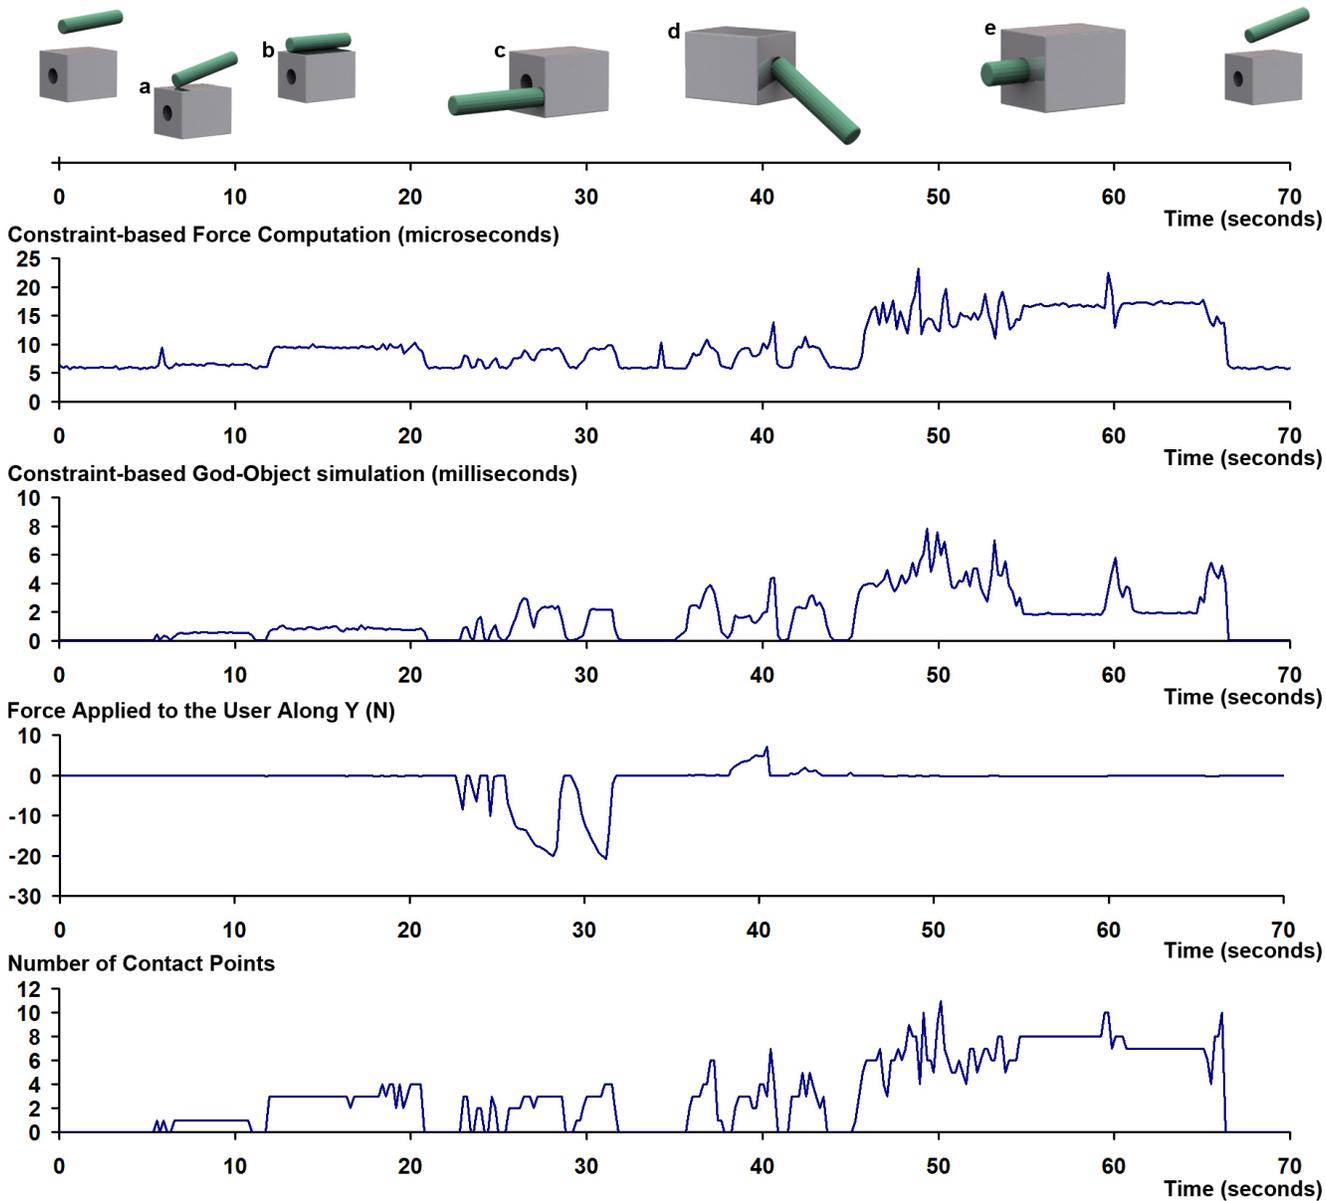

Figure 8: **Performance of our approach in the peg-in-a-hole benchmark.** Our method computes a constraint-based force within a few *microseconds*, while a peg configuration update requires only a few *milliseconds*, which is sufficient to prevent visual lag in the simulation. As expected, the user feels a force in the Y direction only when he pushes the peg on the left side of the box (step (c)) or explores the right extremity of the hole (step (d)). Note how the combination of the collision detection and constraint-based quasi-statics algorithms tend to limit the number of simultaneous contact points during the interaction.
