## ABSTRACT

RDF is the leading data model for the Semantic Web, and dedicated query languages such as SPARQL 1.1, featuring in particular aggregation, allow extracting information from RDF graphs. A framework for analytical processing of RDF data was introduced in [1], where analytical schemas and analytical queries (cubes) are fully re-designed for heterogeneous, semantic-rich RDF graphs. In this novel analytical setting, we consider the following optimization problem: how to reuse the materialized result of a given RDF analytical query (cube) in order to compute the answer to another cube. We provide view-based rewriting algorithms for these cube transformations, and demonstrate experimentally their practical interest.

## 1. MOTIVATION AND OUTLINE

Graph-structured, semantics-rich, heterogeneous RDF data needs dedicated warehousing tools [2]. In [1], we have introduced a novel framework for RDF data analytics. At its core lies the concept of *analytical schema* ( $AnS$ , in short), which reflects a view of the data under analysis. Based on an analytical schema, *analytical queries* ( $AnQ$ , in short) can be posed over the data; they are the counterpart of the “cube” queries in the relational data warehouse scenario, but specific to our RDF context. Just like in the traditional relational data warehouse (DW) setting,  $AnQs$  can be evaluated either on a materialized  $AnS$  instance, or by composing them with the definition of the  $AnS$ ; the latter is more efficient when  $AnQ$  answering only needs a small part of the  $AnS$  instance.

In this work, we focus on efficient OLAP operations for the RDF data warehousing context introduced in [1]. More specifically, we consider the question of computing the answer to an  $AnQ$  based on the (intermediary) answer of another  $AnQ$ , which has been materialized previously. While efficient techniques for such “cube-to-cube” transformations have been widely studied in the relational DW setting, new algorithms are needed in our context, where, unlike the traditional relational DW setting, a fact may have (i) multiple values along each dimension and (ii) multiple measure results.

In the sequel, to make this paper self-contained, Sections 2 recalls the core notions introduced in [1], by borrowing some of its examples; we also recall OLAP operation definitions from that work. Then, we provide novel algorithms for efficiently evaluating such operations on  $AnQs$ , briefly discuss related work, and conclude. An experimental evaluation of our techniques is described in [3].

## 2. BACKGROUND: RDF ANALYTICS

**RDF analytical schemas and queries.** RDF analytical schemas can be seen as *lenses through which data is analyzed*. An  $AnS$  is a labeled directed graph, whose nodes are *analysis classes* and

Figure 1: Sample Analytical Schema ( $AnS$ ).

whose edges are *analysis properties*, deemed interesting by the data analyst for a specific analysis task. The *instance* of an  $AnS$  is built from the base data; it is an RDF graph itself, heterogeneous and semantic-rich, restructured for the needs of the analysis.

Figure 1 shows a sample  $AnS$  for analyzing bloggers and blog posts. An  $AnS$  node is defined by an *unary query*, which, evaluated over an RDF graph, returns a set of URIs. For instance, the node **Blogger** is defined by a query which (in this example) returns the URIs  $user_1$ ,  $user_2$  and  $user_3$ . The interpretation is that the  $AnS$  defines the analysis class **Blogger**, whose instances are these three users. An  $AnS$  edge is defined by a *binary query*, returning pairs of URIs from the base data. The interpretation is that for each (s, o) URI pair returned by the query defining the analysis property p, the triple s p o holds, i.e., o is a value of the property p of s. Crucial for the ability of  $AnSs$  to support analysis of heterogeneous RDF graphs is the fact that  *$AnS$  nodes and edges are defined by completely independent queries*. Thus, for instance, a user may be part of the **Blogger** instance whether or not the RDF graph comprises value(s) for the analysis properties *identifiedBy*, *livesIn* etc. of that user. Further, just like in a regular RDF graph, each blogger may have multiple values for a given analysis property. For instance,  $user_1$  is identified both as *William* and as *Bill*.

We consider the conjunctive subset of SPARQL consisting of *basic graph pattern* (BGP) queries, denoted  $q(\bar{x}) :- t_1, \dots, t_\alpha$ , where  $\{t_1, \dots, t_\alpha\}$  are triple patterns. Unless we explicitly specify that a query has *bag* semantics, the default semantics we consider is that of *set*.

The head of  $q$ , denoted  $head(q)$  is  $q(\bar{x})$ , while the body  $t_1, \dots, t_\alpha$  is denoted  $body(q)$ . We use letters in italics (possibly with subscripts) to denote variables. A *rooted BGP query* is a query  $q$  where each variable is reachable through triples from a distinguished variable, denoted *root*. For instance, the following query is a rooted BGP, whose root is  $x_1$ :

$$q(x_1, x_2, x_3) :- x_1 \text{ acquaintedWith } x_2, \\ x_1 \text{ identifiedBy } y_1, \\ x_1 \text{ wrotePost } y_2, y_2 \text{ postedOn } x_3$$

The query's graph representation below shows that every node is reachable from the root  $x_1$ .

An analytical query consists of two BGP queries homomorphic to the  $AnS$  and rooted in the same  $AnS$  node, and an aggregation function. The first query, called a *classifier*, specifies the facts and the aggregation dimensions, while the second query, called the *measure*, returns the values that will be aggregated for each fact. The measure query has *bag semantics*. Example 1 presents an  $AnQ$  over the  $AnS$  defined in Figure 1.

EXAMPLE 1. (ANALYTICAL QUERY) *The query below asks for the number of sites where each blogger posts, classified by the blogger's age and city:*

$$Q :- \langle c(x, d_{age}, d_{city}), m(x, v_{site}), \text{count} \rangle$$

where the classifier and measure queries are defined by:

$$c(x, d_{age}, d_{city}) :- x \text{ rdf:type Blogger}, \\ x \text{ hasAge } d_{age}, x \text{ livesIn } d_{city} \\ m(x, v_{site}) :- x \text{ rdf:type Blogger}, \\ x \text{ wrotePost } p, p \text{ postedOn } v_{site}$$

The semantics of an analytical query is:

DEFINITION 1. (ANSWER SET OF AN ANALYTICAL QUERY) *Let  $\mathcal{I}$  be the instance of an analytical schema with respect to some RDF graph. Let  $Q :- \langle c(x, d_1, \dots, d_n), m(x, v), \oplus \rangle$  be an analytical query against  $\mathcal{I}$ .*

*The answer set of  $Q$  against  $\mathcal{I}$ , denoted  $ans(Q, \mathcal{I})$ , is:*

$$ans(Q, \mathcal{I}) = \{ \langle d_1^j, \dots, d_n^j, \oplus(q^j(\mathcal{I})) \rangle \mid \\ \langle x^j, d_1^j, \dots, d_n^j \rangle \in c(\mathcal{I}) \text{ and } q^j(\mathcal{I}) \text{ is the bag} \\ \text{of all values } v_k^j \text{ such that } (x^j, v_k^j) \in m(\mathcal{I}) \}$$

where  $q^j(\mathcal{I})$  is a bag containing all measure values  $v$  corresponding to  $x^j$ , and the operator  $\oplus$  aggregates all members of this bag. If  $q^j(\mathcal{I})$  is empty, the aggregated measure is undefined, and  $x_j$  does not contribute to the cube. In the following, for conciseness, we use  $ans(Q)$  to denote  $ans(Q, \mathcal{I})$ , where  $\mathcal{I}$  is considered the working instance of the analytical schema.

In other words, the  $AnQ$  returns each tuple of dimension values from the answer of the classifier query, together with the aggregated result of the measure query for those dimension values. The answer set of an  $AnQ$  can thus be represented as a cube of  $n$  dimensions, holding in each cube cell the corresponding aggregate measure.

The counterpart of a *fact*, in this framework, is any value to which the first variable in the classifier,  $x$  above, is bound, and that has a non-empty answer for the measure query. In RDF, a resource may have zero, one or several values for a given property. Accordingly, in our framework, a *fact may have multiple values for each measure*; in particular, some of these values may be identical, yet they should not be collapsed into one. For instance, if a product is rated by 5 users, one of which rates it  $\star\star\star$  while the four others

rate it  $\star$ , the number of times each value was recorded is important. This is why we assign *bag semantics* to  $q^j(\mathcal{I})$ . In all other contexts, we consider BGPs with *set semantics*; this holds in particular for any classifier query  $c(x, d_1, \dots, d_n)$ .

EXAMPLE 2. (ANALYTICAL QUERY ANSWER) *Consider the  $AnQ$  in Example 1, over the  $AnS$  in Figure 1. Suppose the classifier query's answer set is:*

$$\{ \langle \text{user}_1, 28, \text{Madrid} \rangle, \langle \text{user}_3, 35, \text{NY} \rangle, \langle \text{user}_4, 35, \text{NY} \rangle \}$$

*the measure query is evaluated for each of the three facts, leading to the intermediary results:*

$x^j$	user <sub>1</sub>	user <sub>3</sub>	user <sub>4</sub>
$q^j(\mathcal{I})$	$\{\langle s_1 \rangle, \langle s_1 \rangle, \langle s_2 \rangle\}$	$\{\langle s_2 \rangle\}$	$\{\langle s_3 \rangle\}$

where  $\{\cdot\}$  denotes the bag constructor. Aggregating the sites among the classification dimensions leads to the  $AnQ$  answer:

$$\{ \langle 28, \text{Madrid}, \mathbf{3} \rangle, \langle 35, \text{NY}, \mathbf{2} \rangle \}$$

**OLAP for RDF.** On-Line Analytical Processing (OLAP) [4] technologies enhance the abilities of data warehouses (so far, mostly relational) to answer multi-dimensional analytical queries. In a relational setting, the so-called "OLAP operations" allow computing a cube (the answer to an analytical query) out of another previously materialized cube.

In our data warehouse framework specifically designed for graph-structured, heterogeneous RDF data, a cube corresponds to an  $AnQ$ ; for instance, the query in Example 1 models a bi-dimensional cube on the warehouse related to our sample  $AnS$  in Figure 1. Thus, we model traditional OLAP operations on cubes as  $AnQ$  rewritings, or more specifically, rewritings of *extended  $AnQ$ s* which we introduce below.

DEFINITION 2. (EXTENDED  $AnQ$ ) *Let  $\mathcal{S}$  be an  $AnS$ , and  $d_1, \dots, d_n$  be a set of dimensions, each ranging over a non-empty finite set  $V_i$ . Let  $\Sigma$  be a total function over  $\{d_1, \dots, d_n\}$  associating to each  $d_i$ , either  $V_i$  or a non-empty subset of  $V_i$ . An extended analytical query  $Q$  is defined by a triple:*

$$Q :- \langle c_{\Sigma}(x, d_1, \dots, d_n), m(x, v), \oplus \rangle$$

where  $c$  is a classifier and  $m$  a measure query over  $\mathcal{S}$ ,  $\oplus$  is an aggregation operator, and moreover:

$$c_{\Sigma}(x, d_1, \dots, d_n) = \\ \bigcup_{(\chi_1, \dots, \chi_n) \in \Sigma(d_1) \times \dots \times \Sigma(d_n)} c(x, \chi_1, \dots, \chi_n)$$

In the above, the extended classifier  $c_{\Sigma}(x, d_1, \dots, d_n)$  is the set of all possible classifiers obtained by *replacing each dimension variable  $d_i$  with a value from  $\Sigma(d_i)$* . We introduce  $\Sigma$  to constrain some classifier dimensions, i.e., to restrict the classifier result. The *semantics of an extended analytical query* is derived from the semantics of a standard  $AnQ$  (Definition 1) by replacing the tuples from  $c(\mathcal{I})$  with tuples from  $c_{\Sigma}(\mathcal{I})$ . Thus, an extended analytical query can be seen as a union of a set of standard  $AnQ$ s, one for each combination of values in  $\Sigma(d_1), \dots, \Sigma(d_n)$ . Conversely, an analytical query corresponds to an extended analytical query where  $\Sigma$  only contains pairs of the form  $(d_i, V_i)$ .

We define the following **RDF OLAP operations**:

A SLICE operation binds an aggregation dimension to a single value. Given an extended query  $Q := \langle c_{\Sigma'}(x, d_1, \dots, d_n), m(x, v), \oplus \rangle$ , a SLICE operation over a dimension  $d_i$  with value  $v_i$  returns the extended query  $Q_{\text{SLICE}} := \langle c_{\Sigma'}(x, d_1, \dots, d_n), m(x, v), \oplus \rangle$ , where  $\Sigma' = (\Sigma \setminus \{(d_i, \Sigma(d_i))\}) \cup \{(d_i, \{v_i\})\}$ .

Similarly, a DICE operation constrains several aggregation dimensions to values from specific sets. A DICE on  $Q$  over dimensions  $\{d_{i_1}, \dots, d_{i_k}\}$  and corresponding sets of values  $\{S_{i_1}, \dots, S_{i_k}\}$ , returns the query  $Q_{\text{DICE}} := \langle c_{\Sigma'}(x, d_1, \dots, d_n), m(x, v), \oplus \rangle$ , where  $\Sigma' = (\Sigma \setminus \bigcup_{j=i_1}^{i_k} \{(d_j, \Sigma(d_j))\}) \cup \bigcup_{j=i_1}^{i_k} \{(d_j, S_j)\}$ .

A DRILL-OUT operation on  $Q$  over dimensions  $\{d_{i_1}, \dots, d_{i_k}\}$  corresponds to removing these dimensions from the classifier. It leads to a new query  $Q_{\text{DRILL-OUT}}$  having the classifier  $c_{\Sigma'}(x, d_{j_1}, \dots, d_{j_{n-k}})$ , where  $d_{j_1}, \dots, d_{j_{n-k}} \in \{d_1, \dots, d_n\} \setminus \{d_{i_1}, \dots, d_{i_k}\}$  and  $\Sigma' = (\Sigma \setminus \bigcup_{j=i_1}^{i_k} \{(d_j, \Sigma(d_j))\})$ .

Finally, a DRILL-IN operation on  $Q$  over dimensions  $\{d_{n+1}, \dots, d_{n+k}\}$  which all appear in the classifier's body and have value sets  $\{V_{n+1}, \dots, V_{n+k}\}$  corresponds to adding these dimensions to the head of the classifier. It produces a new query  $Q_{\text{DRILL-IN}}$  having the classifier  $c_{\Sigma'}(x, d_1, \dots, d_n, d_{n+1}, \dots, d_{n+k})$ , where the dimensions  $d_{n+1}, \dots, d_{n+k} \notin \{d_1, \dots, d_n\}$ ,  $\Sigma' = (\Sigma \cup \bigcup_{j=i_1}^{i_k} \{(d_j, V_j)\})$ .

These operations are illustrated in the following example.

**EXAMPLE 3. (OLAP OPERATIONS)** Let  $Q$  be the extended query corresponding to the query-cube defined in Example 1, that is:  $Q := \langle c(x, d_{\text{age}}, d_{\text{city}}), m(x, v_{\text{site}}, \text{count}), \Sigma = \{(d_{\text{age}}, V_{\text{age}}), (d_{\text{city}}, V_{\text{city}})\}$  (the classifier and measure are as in Example 1).

A SLICE operation on the  $d_{\text{age}}$  dimension with value 35 replaces the extended classifier of  $Q$  with  $c_{\Sigma'}(x, d_{\text{age}}, d_{\text{city}}) = \{c(x, 35, d_{\text{city}})\}$  where  $\Sigma' = \Sigma \setminus \{(d_{\text{age}}, V_{\text{age}})\} \cup \{(d_{\text{age}}, \{35\})\}$ .

A DICE operation on both  $d_{\text{age}}$  and  $d_{\text{city}}$  dimensions with values  $\{28\}$  for  $d_{\text{age}}$  and  $\{\text{Madrid}, \text{Kyoto}\}$  for  $d_{\text{city}}$  replaces the extended classifier of  $Q$  with  $c_{\Sigma'}(x, d_{\text{age}}, d_{\text{city}}) = \{c(x, 28, \text{Madrid}), c(x, 28, \text{Kyoto})\}$  where  $\Sigma' = \{(d_{\text{age}}, \{28\}), (d_{\text{city}}, \{\text{Madrid}, \text{Kyoto}\})\}$ .

A DRILL-OUT on the  $d_{\text{age}}$  dimension produces  $Q_{\text{DRILL-OUT}} := \langle c_{\Sigma'}(x, d_{\text{city}}), m(x, v_{\text{site}}, \text{count}) \rangle$  with  $\Sigma' = \{(d_{\text{city}}, V_{\text{city}})\}$  and  $\text{body}(c') \equiv \text{body}(c)$ .

Finally, a DRILL-IN on the  $d_{\text{age}}$  dimension applied to the query  $Q_{\text{DRILL-OUT}}$  above produces  $Q$ , the query of Example 1.

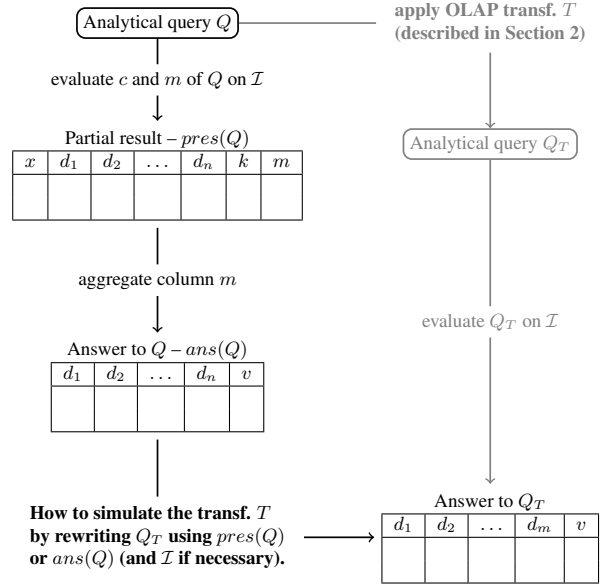

### 3. OPTIMIZED OLAP OPERATIONS

The above OLAP operations lead to new queries, whose answers can be computed based on the  $AnS$  instance. The focus of the present work is on answering such queries by using the materialized results of the initial  $AnQ$ , and (only when that input is insufficient) more data, such as intermediary results generated while computing  $AnQ$  results, or (a small part of) the  $AnS$  instance. These results are often significantly smaller than the full instance, hence obtaining the answer to the new query based on them is likely faster than computing it from the instance. Figure 2 provides a sketch of the problem.

In the following, all relational algebra operators are assumed to have bag semantics.

Given an analytical query  $Q$  whose measure query (with bag semantics) is  $m$ , we denote by  $\bar{m}$  the *set-semantics* query whose body is the same as the one of  $m$  and whose head comprises *all the variables of  $m$ 's body*. Obviously, there is a bijection between the bag result of  $m$  and the set result of  $\bar{m}$ . Using  $\bar{m}$ , we define next the intermediary answer of an  $AnQ$ .

**DEFINITION 3. (INTERMEDIARY QUERY OF AN  $AnQ$ )** Let  $Q :=$

**Figure 2: Problem statement.**

$\langle c, m, \oplus \rangle$  be an  $AnQ$ . The intermediary query of  $Q$ , denoted  $int(Q)$ , is:

$$int(Q) = c(x, d_1, \dots, d_n) \bowtie_x \bar{m}(x, v)$$

It is easy to see that  $int(Q)$  holds *all the information needed in order to compute both  $c$  and  $m$* ; it holds *more information* than the results of  $c$  and  $m$ , given that it preserves all the different embeddings of the (bag-semantics)  $m$  query in the data. Clearly, evaluating  $int$  is at least as expensive as evaluating  $Q$  itself; while  $int$  is conceptually useful, we do not need to evaluate it or store its results.

Instead, we propose to evaluate (possibly as part of the effort for evaluating  $Q$ ), *store and reuse* a more compact result, defined as follows. For a given query  $Q$  whose measure (with bag semantics) is  $m$ , we term *extended measure result* over an instance  $\mathcal{I}$ , denoted  $m^k(\mathcal{I})$ , the set defined by:

$$\{(newk(), t) \mid t \in m(\mathcal{I})\}$$

where  $newk()$  is a key-creating function returning a distinct value at each call. A very simple implementation of  $newk()$ , which we will use for illustration, returns successively 1, 2, 3 etc. We assign a key to each tuple in the measure so that multiple identical values of a given measure for a given fact would not be erroneously collapsed into one. For instance, if

$$m(\mathcal{I}) = \{(x_1, m_1), (x_1, m_1), (x_1, m_2), (x_2, m_3)\},$$

then

$$m^k(\mathcal{I}) = \{(1, x_1, m_1), (2, x_1, m_1), (3, x_1, m_2), (4, x_2, m_3)\}.$$

**DEFINITION 4. (PARTIAL RESULT OF AN  $AnQ$ )** Let  $Q := \langle c, m, \oplus \rangle$  be an  $AnQ$ . The partial result of  $Q$  on an instance  $\mathcal{I}$ , denoted  $pres(Q, \mathcal{I})$  is:

$$pres(Q, \mathcal{I}) = c(\mathcal{I}) \bowtie_x m^k(\mathcal{I})$$

One can see  $pres(Q, \mathcal{I})$  as the input to the last aggregation performed in order to answer the  $AnQ$ , *augmented with a key*. In the

following, we use  $pres(Q)$  to denote  $pres(Q, \mathcal{I})$  for the working instance of the  $AnS$ .

**Problem Statement :** (ANSWERING  $AnQs$  USING THE MATERIALIZED RESULTS OF OTHER  $AnQs$ ) Let  $Q, Q_T$  be  $AnQs$  such that applying the OLAP transformation  $T$  on  $Q$  leads to  $Q_T$ . The problem of answering  $Q_T$  using the materialized result of  $Q$  consists of finding: (i) an equivalent rewriting of  $Q_T$  based on  $pres(Q)$  or  $ans(Q)$ , if one exists; (ii) an equivalent rewriting of  $Q_T$  based on  $pres(Q)$  and the  $AnS$  instance, otherwise.

Importantly, the following holds:

$$\pi_{x, d_1, \dots, d_n, v}(int(Q)(\mathcal{I})) = \pi_{x, d_1, \dots, d_n, v}(pres(Q, \mathcal{I})) \quad (1)$$

$$Q \equiv \gamma_{d_1, \dots, d_n, \oplus(v)}(\pi_{x, d_1, \dots, d_n, v}(int(Q))) \quad (2)$$

$$ans(Q)(\mathcal{I}) = \gamma_{d_1, \dots, d_n, \oplus(v)}(\pi_{x, d_1, \dots, d_n, v}(pres(Q, \mathcal{I}))) \quad (3)$$

Equation (1) directly follows from the definition of  $pres$ . Equation (2) will be exploited to establish the correctness of some of our techniques. Equation (3) above is the one on which our rewriting-based  $AnQ$  answering technique is based.

### 3.1 Slice and Dice

In the case of SLICE and DICE operations, the data cube transformation is made simply by row selection over the materialized final results of an  $AnQ$ .

**EXAMPLE 4. (DICE)** *The query  $Q$  asks for the average number of words in blog posts, for each blogger's age and residential city.*

$$Q :- \langle c(x, d_{age}, d_{city}), m(x, v_{words}), average \rangle$$

$$\begin{aligned} c(x, d_{age}, d_{city}) &:- x \text{ rdf:type Blogger,} \\ &\quad x \text{ hasAge } d_{age}, x \text{ livesIn } d_{city} \\ m(x, v_{words}) &:- x \text{ rdf:type Blogger,} \\ &\quad x \text{ wrotePost } p, \\ &\quad p \text{ hasWordCount } v_{words} \end{aligned}$$

Suppose the answer of  $c$  over  $\mathcal{I}$  is

$$\{\langle user_1, 28, Madrid \rangle, \langle user_3, 35, NY \rangle, \langle user_4, 28, Madrid \rangle\}$$

and the answer of  $m$  over  $\mathcal{I}$  is

$$\{\langle user_1, 100 \rangle, \langle user_1, 120 \rangle, \langle user_3, 570 \rangle, \langle user_4, 410 \rangle\}$$

Joining the answers of  $c$  and  $m$  in such a query results in:

$$\{\langle user_1, 28, Madrid, 100 \rangle, \langle user_1, 28, Madrid, 120 \rangle, \langle user_3, 35, NY, 570 \rangle, \langle user_4, 28, Madrid, 410 \rangle\}$$

The final answer to  $Q$  after aggregation is:

$$\{\langle 28, Madrid, 210 \rangle, \langle 35, NY, 570 \rangle\}$$

The query  $Q_{DICE}$  is the result of a DICE operation on  $Q$ , restricting the  $d_{age}$  to values between 20 and 30.  $Q_{DICE}$  differs from  $Q$  only by its classifier which can be written as  $c_{\Sigma'}(x, d_{age}, d_{city})$  where  $\Sigma' = \Sigma \setminus \{(d_{age}, V_{age})\} \cup \{(d_{age}, \{d_{age}\}_{20 \leq d_{age} \leq 30})\}$ .

Applying DICE on the answer to  $Q$  above yields the result:

$$\{\langle 28, Madrid, 210 \rangle\}$$

Now, we calculate the answer to  $Q_{DICE}$ . The result of the classifier query  $c_{\Sigma'}$ , obtained by applying a selection on the  $d_{age}$  dimension is:

$$\{\langle user_1, 28, Madrid \rangle, \langle user_4, 28, Madrid \rangle\}$$

Evaluating  $m$  and joining its result with the above set yields:

$$\{\langle user_1, 28, Madrid, 100 \rangle, \langle user_1, 28, Madrid, 120 \rangle, \langle user_4, 28, Madrid, 410 \rangle\}$$

The final answer to  $Q_{DICE}$  after aggregation is:

$$\{\langle 28, Madrid, 210 \rangle\}$$

DICE applied over the answer of  $Q$  yields the answer of  $Q_{DICE}$ .

**DEFINITION 5. (SELECTION)** Let  $dice$  be a dice operation on analytical queries. Let  $\Sigma'$  be the function introduced in Definition 2. We define a selection  $\sigma_{dice}$  as a function on the space of analytical query answers  $ans(Q)$  where:

$$\begin{aligned} \sigma_{dice}(ans(Q)) &= \{\langle d_1, \dots, d_n, v \rangle \mid \langle d_1, \dots, d_n, v \rangle \in ans(Q) \\ &\quad \wedge \forall i \in \{1, \dots, n\} d_i \in \Sigma'(d_i)\} \end{aligned}$$

**PROPOSITION 1.** Let  $Q :- \langle c_{\Sigma}(x, d_1, \dots, d_n), m(x, v), \oplus \rangle$  and  $Q_{DICE} :- \langle c'_{\Sigma'}(x, d_1, \dots, d_n), m'(x, v), \oplus \rangle$  be two analytical queries such that query  $Q_{DICE} = dice(Q)$ . Then  $\sigma_{dice}(ans(Q)) = ans(Q_{DICE})$ .

The proofs for all our results can be found in [3].

### 3.2 Drill-Out

Unlike the relational DW setting, in our RDF warehousing framework the result of a drill-out operation (that is, the answer to  $Q_{DRILL-OUT}$ ) cannot be correctly computed directly from the answer to the original query  $Q$ , and here is why. Each tuple in  $ans(Q)$  binds a set of dimension values to an aggregated measure. In fact, each such tuple represents a set of facts having the same dimension values. Projecting a dimension out will make some of these sets merge into one another, requiring a new aggregation of the measure values. Computing this new aggregated measure from the ones in  $ans(Q)$  will require considering whether the aggregation function has the distributive property, i.e., whether  $\oplus(a, \oplus(b, c)) = \oplus(\oplus(a, b), c)$ .

1. *Distributive aggregation function, e.g. sum.* In this case, the new aggregated measure value could be computed from  $ans(Q)$  if the sets of facts aggregated in each tuple of  $ans(Q)$  were mutually exclusive. This is not the case in our setting where each fact can have several values along the same dimension. Thus, aggregating the already aggregated measure values will lead to erroneously consider some facts more than once; avoiding this requires being able to trace the measure results back to the facts they correspond to.
2. *Non-distributive aggregation function, e.g., avg.* For such functions, the new aggregated measure must be computed from scratch.

Based on the above discussion, we propose Algorithm 1 to compute the answer to  $Q_{DRILL-OUT}$ , using the partial result of  $Q$ , denoted  $pres(Q)$  above, which we assume has been materialized and stored as part of the evaluation of the original query  $Q$ . This deduplication ( $\delta$ ) step is needed, since some facts may have been repeated in  $T$  for being multivalued along  $d_i$ . The aggregation function  $\oplus$  is applied to the measure column of the resulting relation  $T$ , using  $\gamma$ , grouping the tuples along the dimensions  $d_1, \dots, d_{i-1}, d_{i+1}, \dots, d_n$ .

Proposition 2 states the correctness of Algorithm 1.

**Algorithm 1** DRILL-OUT cube transformation

- 1: **Input:**  $pres(Q), d_i$
- 2:  $T \leftarrow \Pi_{root, d_1, \dots, d_{i-1}, d_{i+1}, \dots, d_n, k, v}(pres(Q))$
- 3:  $T \leftarrow \delta(T)$
- 4:  $T \leftarrow \gamma_{d_1, \dots, d_{i-1}, d_{i+1}, \dots, d_n, \oplus}(v)(T)$
- 5: **return**  $T$

PROPOSITION 2. Let  $Q$  be an AnQ and  $Q_{DRILL-OUT}$  be the AnQ obtained from  $Q$  by drilling out along the dimension  $d_i$ . Algorithm 1 applied on  $pres(Q)$  and  $d_i$  computes  $ans(Q_{DRILL-OUT})$ .

Example 5 illustrates Algorithm 1, and also shows how relying only on  $ans(Q)$  may introduce errors.

EXAMPLE 5. (DRILL-OUT) Consider an analytical query  $Q$  such that its classifier  $c_1$ , measure  $m$  and intermediary answer  $pres(Q)$  have the results shown below.

root	$d_1$	...	$d_{n-1}$	$d_n$
$x$	$a_1$	...	$a_{n-1}$	$a_n$
$x$	$a_1$	...	$a_{n-1}$	$b_n$
$y$	$a_1$	...	$a_{n-1}$	$b_n$

$k$	root	$v$
1	$x$	$m_1$
2	$y$	$m_2$

root	$d_1$	...	$d_{n-1}$	$d_n$	$k$	$v$
$x$	$a_1$	...	$a_{n-1}$	$a_n$	1	$m_1$
$x$	$a_1$	...	$a_{n-1}$	$b_n$	1	$m_1$
$y$	$a_1$	...	$a_{n-1}$	$b_n$	2	$m_2$

 (i)

Let  $Q_{DRILL-OUT}$  be the result of a DRILL-OUT operation on  $Q$  eliminating dimension  $d_n$ . The measure of  $Q_{DRILL-OUT}$  is still  $m$ , while its classifier  $c_2$  has the answer shown next:

root	$d_1$	...	$d_{n-1}$
$x$	$a_1$	...	$a_{n-1}$
$y$	$a_1$	...	$a_{n-1}$

Note that  $c_2$  returns only one row for  $x$ , because it has one value for the dimension vector  $\langle d_1, \dots, d_{n-1} \rangle$ .  $pres(Q_{DRILL-OUT})$  yields:

root	$d_1$	...	$d_{n-1}$	$k$	$v$
$x$	$a_1$	...	$a_{n-1}$	1	$m_1$
$y$	$a_1$	...	$a_{n-1}$	2	$m_2$

Applying aggregation over the above table leads to:

$d_1$	...	$d_{n-1}$	$v$
$a_1$	...	$a_{n-1}$	$\oplus(\{m_1, m_2\})$

 (ii)

Algorithm 1 on the input (i), first projects out  $d_n$ . Table  $T$  after projecting out  $d_n$  from  $pres(Q)$  is:

root	$d_1$	...	$d_{n-1}$	$k$	$v$
$x$	$a_1$	...	$a_{n-1}$	1	$m_1$
$x$	$a_1$	...	$a_{n-1}$	1	$m_1$
$y$	$a_1$	...	$a_{n-1}$	2	$m_2$

After eliminating duplicates ( $\delta(T)$ ), grouping and aggregation, we obtain:

$d_1$	...	$d_{n-1}$	$v$
$a_1$	...	$a_{n-1}$	$\oplus(\{m_1, m_2\})$

 (iii)

The output of Algorithm 1 above, denoted (iii), is the same as (ii), showing that our algorithm answers  $Q_{DRILL-OUT}$  correctly using the intermediary answer of  $Q$ .

Next we examine what would happen if an algorithm took the answer of  $Q$  as input. First, we compute  $ans(Q)$ , by aggregating the measures along the dimensions from the intermediary result depicted in (i):

$d_1$	...	$d_{n-1}$	$d_n$	$v$
$a_1$	...	$a_{n-1}$	$a_n$	$\oplus(\{m_1\})$
$a_1$	...	$a_{n-1}$	$b_n$	$\oplus(\{m_1, m_2\})$

Next we project out  $d_n$  from  $ans(Q)$ :

$d_1$	...	$d_{n-1}$	$v$
$a_1$	...	$a_{n-1}$	$\oplus(\{m_1\})$
$a_1$	...	$a_{n-1}$	$\oplus(\{m_1, m_2\})$

and aggregate, assuming that  $\oplus$  is distributive.

$d_1$	...	$d_{n-1}$	$v$
$a_1$	...	$a_{n-1}$	$\oplus(\{m_1, m_1, m_2\})$

 (iv)

Observe that (iv) is different from (ii). More specifically, the measure value corresponding to the multi-valued entity  $x$  has been considered twice in the aggregated measure value of (iv).

### 3.3 Drill-In

The drill-in operation increases the level of detail in a cube by adding a new dimension. In general, this additional information is not present in the answer of the original query. Hence, answering the new query requires extra information.

**Algorithm 2** DRILL-IN cube transformation

- 1: **Input:**  $pres(Q, \mathcal{I}), c, d_{n+1}$
- 2: build  $q_{aux}^Q(dvars, d_{n+1})$  :- body ▷ as per Definition 6
- 3:  $T \leftarrow pres(Q, \mathcal{I}) \bowtie_{dvars} q_{aux}^Q(\mathcal{I})$
- 4:  $T \leftarrow \gamma_{d_1, \dots, d_n, d_{n+1}, \oplus}(v)(T)$
- 5: **return**  $T$

Algorithm 2 uses the partial result of  $Q$ , denoted  $pres(Q)$ , and consults the materialized AnS instance to obtain the missing information necessary to answer  $Q_{DRILL-IN}$ . We retrieve this information through an auxiliary query defined as follows.

DEFINITION 6. (AUXILIARY DRILL-IN QUERY) Let  $Q$  :-  $\langle c(x, d_1, \dots, d_n, m(x, v), \oplus) \rangle$  be an AnQ and  $d_{n+1}$  a non-distinguished variable in  $c$ . The auxiliary DRILL-IN query of  $Q$  over  $d_{n+1}$  is a conjunctive query  $q_{aux}^Q(dvars, d_{n+1})$  :- body $_{aux}$ , where

- each triple  $t \in body(c)$  containing the variable  $d_{n+1}$  is also in  $body_{aux}$ ;

URL2	chrome	n

$ans(Q_{DRILL-IN})$

x	d <sub>2</sub>	d <sub>3</sub>	k	v
video1	URL1	firefox	1	n
video1	URL2	chrome	1	n

**Figure 3: DRILL-IN example.**

- for each triple  $t_{aux}$  in  $body_{aux}$  and  $t$  in the body of  $c$  such that  $t$  and  $t_{aux}$  share a non-distinguished variable of  $c$ , the triple  $t$  also belongs to  $body_{aux}$ ;
- each variable in  $body_{aux}$  that is distinguished in  $c$  is a distinguished variable  $q_{aux}^Q$ .

The auxiliary query  $q_{aux}^Q$  comprises all triples from  $Q$ 's classifier having the dimension  $d_{n+1}$ ; to these, it adds all the classifier triples sharing a *non-distinguished (existential)* variable with the former; then all the classifier triples sharing an existential variable with a triple previously added to  $body_{aux}$  etc. This process stops when there are no more existential variables to consider. The variables distinguished in  $c$ , together with the new dimension  $d_{n+1}$ , are distinguished in  $q_{aux}^Q$ .

**PROPOSITION 3.** *Let  $Q := \langle c, m, \oplus \rangle$  be an analytical query and  $d_{n+1}$  be a non-distinguished variable in  $c$ . Let  $Q_{DRILL-IN}$  be the analytical query obtained from  $Q$  by drilling in along the dimension  $d_{n+1}$ , and  $\mathcal{I}$  be an instance. Algorithm 2 applied on  $pres(Q, \mathcal{I})$ ,  $c$  and  $d_{n+1}$  computes  $ans(Q_{DRILL-IN})(\mathcal{I})$ .*

**EXAMPLE 6. (DRILL-IN REWRITING)** *Let  $Q := \langle c, m, \text{sum} \rangle$  be the following AnQ:*

$c(x, d_2) :- x \text{ rdf:type Video}, x \text{ uploadedOn } d_1,$   
 $$d_1 \text{ hasUrl } d_2, d_1 \text{ supportsBrowser } d_3$$   
 $m(x, v) :- x \text{ rdf:type Video}, x \text{ viewNum } v$

$Q_{DRILL-IN}$  is the result of a DRILL-IN that adds the dimension  $d_3$ , having the classifier query  $c'(x, d_2, d_3)$ .

Figure 3 shows the materialized analytical schema instance, the partial and final answer to  $Q$ , and the partial and final answer to  $Q_{DRILL-IN}$ . Now, let us see how to answer  $Q_{DRILL-IN}$  using Algorithm 2. We have:

$q_{aux}^Q(x, d_2, d_3) :- x \text{ postedOn } d_1, d_1 \text{ hasUrl } d_2,$   
 $$d_1 \text{ supportsBrowser } d_3$$

Based on  $\mathcal{I}$ , the answer to  $q_{aux}^Q$  is:

x	d <sub>2</sub>	d <sub>3</sub>
video1	URL1	firefox
video1	URL2	chrome

Joining the above with  $pres(Q)$  yields the last table in Figure 3, which after aggregation yields the result of  $Q_{DRILL-IN}$ .

## 4. RELATED WORK

Previous RDF data management research focused on efficient stores, query processing, view selection etc. BGP query answering techniques have been studied intensively, e.g., [5, 6], and some are deployed in commercial systems such as Oracle 11g's "Semantic Graph" extension. Our optimizations can be deployed on top of any RDF data management platform, to extend it with optimized analytic capabilities.

The techniques we presented can be seen as a particular case of view-based rewriting [7], where partial AnQ results are used as a materialized view. Novel algorithms were required due to the novel AnQ language we introduced in [1].

SPARQL 1.1 [8] features SQL-style grouping and aggregation, less expressive than our AnQs, as our measure queries allow more flexibility than SPARQL. Thus, the OLAP operation optimizations we presented can also apply to the more restricted SPARQL analytical context.

OLAP has been thoroughly studied in a relational setting, where it is at the basis of a successful industry; in particular, OLAP operation evaluation by reusing previous cube results is well-known. The heterogeneity of RDF, which in turn justified our novel RDF analytics framework [1], leads to the need for the novel algorithms we described here, which are specific to this setting.

## 5. CONCLUSION

Our work focused on optimizing the OLAP transformations in the RDF data warehousing framework we introduced in [1], by using view-based rewriting techniques. To this end, for each OLAP operation, we introduced an algorithm that answers a transformed query based on the final or on an intermediary result of the original analytical query. We formally prove the correctness of our techniques, and describe experiments performed with our algorithms, in our technical report [3].
