ABSTRACT

Terahertz frequency band is an emerging research area related to nano-scale communications. In this frequency range, specific features can provide the possibility to overcome the issues related to the spectrum scarcity and capacity limitation. Apart high molecular absorption, and very high reflection loss that represent main phenomena in THz band, we can derive the characteristics of the channel affected by chirality effects occurring in the propagation medium, specifically, in the case where a Giant Optical Activity is present. This effect is typical of the so-called chiral-metamaterials in (4–10) THz band, and is of stimulating interest particularly for millimeter wireless communications.
In this paper, we analyze the behavior of specific parameters of a chiral-metamaterial, like the relative electrical permittivity, magnetic permeability and chirality coefficients, and from that we derive the channel behavior both for Line-of-Sight and No Line-of-Sight propagations. We notice the presence of spectral windows, due to peaks of resonance of chiral parameter. Finally, performances of the chirality-affected channel have been assessed in terms of (i) channel capacity, (ii) propagation delay, and (iii) coherence bandwidth, for different distances.

Keywords

THz band, chirality effects, Giant Optical Activity, nano-communications

1. INTRODUCTION

The increasing demand of wireless nanocommunication systems following the framework of Internet of NanoThings [1] has motivated the need to design accurate channel models working in the Terahertz band [2,3]. This frequency band represents one of the most promising spectrum bands to enable ultra-high-speed communications, with the aim to overcome the spectrum scarcity and capacity limitations of current wireless systems. Indeed, existing channel models adopted for lower frequency bands cannot be re-used for THz communications.

Many researchers have already presented novel channel models for THz band [4–8], where molecular absorption and spreading loss are the main features studied in this frequency range. Another work [9] considers a multi-ray approach by assuming reflected, scattered and diffracted paths, in order to model the main THz-band channel features, such as the distance-varying spectral windows, and the temporal broadening effects.

As it can be noticed from previous works, the channel modeling in THz band is addressed through transfer functions that consider specific features, like molecular absorption loss, and spreading loss. However, there are other effects that deserve to be considered and analyzed, such as the electromagnetic chirality effect and the specific features of the propagation medium, that are normally neglected in classical modeling of transmission channels. The relative chirality parameter is a specific characteristic of a chiral homogeneous isotropic medium. Standard values are in the range $[0, 1]$, but in particular media such as the chiral complex materials where a Giant Optical Activity (GOA) takes place, the relative chirality parameter is complex and varies with the frequency, showing multiple peaks at specific resonance frequencies [10]. A material that exhibits a GOA and is affected by the chirality effects is called *chiral-metamaterial* [11]. This is an artificial material that shows a frequency-dependent cross-coupling between the electric and magnetic fields. This interesting property is of great interest to many areas of science, like analytical chemistry and molecular biology.

In this paper, we consider a chiral-metamaterial exhibiting a GOA, and we analyze the specific behavior of channel transfer function in case of direct and multi-path propagation, in the (4–10) THz frequency range. Due to the resonant behavior of chiral parameter, the channel model shows specific frequency-dependent spectral windows, guaranteeing high bandwidth values.

This paper is organized as follows. In Section 2 we introduce the frequency-dependent behavior of specific parameters of a chiral-metamaterial. Starting from the concept of electromagnetic chirality [12–14], we consider the chiral effects following the change in the propagation velocity and in the refractive index, due to the chiral impurities inside the propagation medium. These effects are evaluated also in the case when the considered medium exhibits a GOA [10, 15]. Then, in Section 3 we derive the corresponding chirality-affected channel model for THz band, and present the re-

lated frequency-dependent spectral windows. Section 4 is then devoted to the performances of the chiral channel, assessed in terms of capacity, propagation delay, and coherence bandwidth, in case of LoS and NLoS propagation modes. Finally, conclusions are drawn at the end of the paper.

2. FULL-WAVE PROPAGATION IN A CHIRAL-METAMATERIAL

This section is devoted to the design of a full-wave propagation model for THz band, when a GOA is working. Starting from the classic harmonic macroscopic Maxwell's equations, we consider the electromagnetic propagation inside a generic complex material, under the assumption that it is a linear and chiral medium.

Unconventional materials (*i.e.* metamaterials) are specifically considered since the GOA is reinforced by using thin metallic crossed-structure impurities in the host dielectric medium, that is chiral-metamaterials [11]. Therefore, we will consider a time-harmonic generic linear material, where chiral (magneto/electric-optical) effects are included in the following constitutive relations, that can be written as:

$$\begin{cases} \mathbf{B} = \underline{\xi} \bullet \mathbf{E} + \underline{\mu} \bullet \mathbf{H} \\ \mathbf{D} = \underline{\varepsilon} \bullet \mathbf{E} + \underline{\zeta} \bullet \mathbf{H} \end{cases} \tag{1}$$

where we remind that $\mathbf{B}$ is the magnetic displacement and $\mathbf{H}$ is the magnetic field, as well as $\mathbf{D}$ is the electric displacement and $\mathbf{E}$ is the electric field. Finally, the symbol $\bullet$ represents the scalar product operator, and $\underline{\xi}$, $\underline{\mu}$, $\underline{\varepsilon}$, and $\underline{\zeta}$ are specific tensor quantities of the material.

From (1) we observe the chirality property through the dependence of (i) $\mathbf{E}$ in $\mathbf{B}$, and (ii) $\mathbf{H}$ in $\mathbf{D}$. Furthermore, the displacement field existing inside the material is generated by an excitation expressed in terms of intensity of the incident electro-magnetic field. Therefore, the material under consideration is a linear chiral medium.

We remind that the chiral effects have a two-fold meaning *i.e.*, (i) an electric field applied on the material provides not only an electric induction, but also a magnetic displacement, and (ii) a magnetic field applied on the material provides not only a magnetic induction, but also an electric displacement, unlikely from other non-chiral materials.

As previously said, in this paper our attention is devoted to a particular class of chiral-metamaterials (GOA). In [16], the authors show that for a GOA reciprocal material the specific constitutive relations are as follows:

$$\begin{bmatrix} \mathbf{B} \\ \mathbf{D} \end{bmatrix} = \begin{bmatrix} -j\frac{\xi_0 \xi_r}{c} & \mu_0 \mu_r \\ \varepsilon_0 \varepsilon_r & j\frac{\xi_0 \xi_r}{c} \end{bmatrix} \bullet \begin{bmatrix} \mathbf{E} \\ \mathbf{H} \end{bmatrix}, \tag{2}$$

where it is clear that the natural dielectric (where ε_b and μ_b are the permittivity and permeability, respectively) becomes a metamaterial. Moreover, for a GOA material, at the frequency around 5 THz and 8 THz, there are four resonance frequencies of the ξ_r relative chirality parameter *i.e.*, $[4.8, 5.6, 7.9, 8.2]$ THz.

The same consideration is applied to the relative permittivity and permeability parameters, still in the (4–10) THz band. As reported in [10], ε_r and μ_r are complex parameters, and the real part has a frequency-dependent behavior, with resonant peaks. Figure 1 (a), (b), and (c) depict the trends of real parts of ε_r, μ_r, and ξ_r, respectively, where it is easy to observe the resonant peaks.

Equation (2) becomes

$$\begin{bmatrix} \mathbf{B} \\ \mathbf{D} \end{bmatrix} = \\ = \begin{bmatrix} -j\frac{\Omega_\xi \omega_0 \omega}{\omega_0^2 - \omega^2 - j\omega\gamma} & \mu_0 \left(\mu_b + \frac{\Omega_\mu \omega^2}{\omega_0^2 - \omega^2 - j\omega\gamma}\right) \\ \varepsilon_0 \left(\varepsilon_b + \frac{\Omega_\varepsilon \omega_0^2}{\omega_0^2 - \omega^2 - j\omega\gamma}\right) & j\frac{\Omega_\xi \omega_0 \omega}{\omega_0^2 - \omega^2 - j\omega\gamma} \end{bmatrix} \bullet \begin{bmatrix} \mathbf{E} \\ \mathbf{H} \end{bmatrix}, \tag{3}$$

where $\omega = 2\pi f$, ε_0, and μ_0 are the absolute permittivity and permeability, respectively. Then, the constitutive parameters of interest are:

$$\varepsilon = \varepsilon_0 \varepsilon_r = \varepsilon_0 \left[\varepsilon_b + \Omega_\varepsilon \omega_0^2 \left(\frac{\omega_0^2 - \omega^2 + j\omega\gamma}{\left(\omega_0^2 - \omega^2\right)^2 + \omega^2 \gamma^2}\right)\right], \tag{4}$$

$$\mu = \mu_0 \mu_r = \mu_0 \left[\mu_b + \Omega_\mu \omega^2 \left(\frac{\omega_0^2 - \omega^2 + j\omega\gamma}{\left(\omega_0^2 - \omega^2\right)^2 + \omega^2 \gamma^2}\right)\right], \tag{5}$$

$$\xi_r = \Omega_\xi \omega_0 \omega \left(\frac{\omega_0^2 - \omega^2 + j\omega\gamma}{\left(\omega_0^2 - \omega^2\right)^2 + \omega^2 \gamma^2}\right). \tag{6}$$

It is noted that the frequency resonant behavior of ξ_r is a like-Drude one, and Ω_ε, Ω_μ, Ω_ξ, γ, and ω_0 are specific parameters of the GOA material [16].

By simple computations, and assuming a lossy material

i.e.,

$$\begin{cases} \varepsilon_b = \mathrm{Re}\left[\varepsilon_b\right] + j\mathrm{Im}\left[\varepsilon_b\right] \\ \mu_b = \mathrm{Re}\left[\mu_b\right] + j\mathrm{Im}\left[\mu_b\right] \end{cases} \tag{7}$$

we obtain

$$\begin{aligned} \varepsilon_r &= \left(\mathrm{Re}\left[\varepsilon_b\right] + \frac{\omega_0^2\left(\omega_0^2-\omega^2\right)\Omega_\varepsilon}{\left(\omega_0^2-\omega^2\right)^2+\omega^2\gamma^2}\right) + \\ &\quad j\left(\frac{\gamma\omega_0^2\Omega_\varepsilon\omega}{\left(\omega_0^2-\omega^2\right)^2+\omega^2\gamma^2} + \mathrm{Im}\left[\varepsilon_b\right]\right), \end{aligned} \tag{8}$$

$$\begin{aligned} \mu_r &= \left(\mathrm{Re}\left[\mu_b\right] + \frac{\omega^2\left(\omega_0^2-\omega^2\right)\Omega_\mu}{\left(\omega_0^2-\omega^2\right)^2+\omega^2\gamma^2}\right) + \\ &\quad j\left(\frac{\gamma\Omega_\mu\omega^3}{\left(\omega_0^2-\omega^2\right)^2+\omega^2\gamma^2} + \mathrm{Im}\left[\mu_b\right]\right), \end{aligned} \tag{9}$$

$$\xi_r = \omega_0\Omega_\xi\left[\frac{\omega\left(\omega_0^2-\omega^2\right)}{\left(\omega_0^2-\omega^2\right)^2+\omega^2\gamma^2}\right] + j\omega_0\Omega_\xi\left[\frac{\gamma\omega^2}{\left(\omega_0^2-\omega^2\right)^2+\omega^2\gamma^2}\right]. \tag{10}$$

Now, by posing the following expression for the square relative refractive index:

$$\begin{aligned} &\varepsilon_r\mu_r + \xi_r^2 = \left(\mathrm{Re}\left[\varepsilon_r\right] + j\mathrm{Im}\left[\varepsilon_r\right]\right)\left(\mathrm{Re}\left[\mu_r\right] + j\mathrm{Im}\left[\mu_r\right]\right) + \\ &+\left(\mathrm{Re}\left[\xi_r\right] + j\mathrm{Im}\left[\xi_r\right]\right)^2 > 0, \end{aligned} \tag{11}$$

we observe that the following conditions hold for a GOA material:

$$\Omega_\varepsilon = \left(1 + \frac{\gamma^2}{\omega^2-\omega_0^2}\right)\mathrm{Re}\left[\varepsilon_b\right], \tag{12}$$

$$\Omega_\mu = \left(1 + \frac{\gamma^2}{\omega^2-\omega_0^2}\right)\mathrm{Re}\left[\mu_b\right], \tag{13}$$

$$\Omega_\xi = \left(1 + \frac{\gamma^2}{\omega^2-\omega_0^2}\right)\sqrt{\mathrm{Re}\left[\varepsilon_b\right]\mathrm{Re}\left[\mu_b\right]}. \tag{14}$$

It is observed that relations (12), (13), and (14) state the connection between the host material parameters *i.e.*, ε_b, and μ_b, and the specific GOA ones in order to obtain a positive refractive index in (11).

Finally, the computation of the electro-magnetic field in the channel is carried out through the solutions of linear differential equations, arising from the following source-less Maxwell's equations:

$$\begin{cases} \left(\underline{\nabla} + j\omega\underline{\xi}\right)\bullet\mathbf{E} = -j\omega\underline{\mu}\bullet\mathbf{H} \\ \left(\underline{\nabla} - j\omega\underline{\zeta}\right)\bullet\mathbf{H} = j\omega\underline{\varepsilon}\bullet\mathbf{E} \end{cases} \tag{15}$$

and the solving differential equations for $\mathbf{E}$ and $\mathbf{H}$ are given, respectively:

$$\begin{cases} \left[\left(\underline{\nabla} - j\omega\underline{\zeta}\right)\bullet\underline{\mu}^{-1}\bullet\left(\underline{\nabla} + j\omega\underline{\xi}\right) - \omega^2\underline{\varepsilon}\right]\bullet\mathbf{E} = 0 \\ \left[\left(\underline{\nabla} + j\omega\underline{\xi}\right)\bullet\underline{\varepsilon}^{-1}\bullet\left(\underline{\nabla} - j\omega\underline{\zeta}\right) - \omega^2\underline{\mu}\right]\bullet\mathbf{H} = 0 \end{cases} \tag{16}$$

where $\underline{\nabla}$ is Kong's operator.

Finally, by assuming the linear polarization of the electric field (*i.e.*, $\mathbf{E} = E_x\hat{\mathbf{x}}$), we obtain the final differential equation for E_x, *i.e.*

$$\alpha_1 E_x + \alpha_2\frac{\partial E_x}{\partial x} + \alpha_3\frac{\partial E_x}{\partial y} + \alpha_4\frac{\partial E_x}{\partial z} + \alpha_5\frac{\partial^2 E_x}{\partial y^2} + \alpha_6\frac{\partial^2 E_x}{\partial z^2} = 0, \tag{17}$$

where α_i with $i = (1, 2, \ldots, 6)$ are coefficients depending on the elements of $\underline{\varepsilon}$, $\underline{\mu}$, $\underline{\xi}$, and $\underline{\zeta}$ tensors.

3. CHIRAL CHANNEL MODEL

In this section, we present how the relative chiralilty parameter affects the channel performance in the (4–10) THz band, in the case of ray tracing propagation (*i.e.*, LoS, and NLoS), and under the linear polarization hypothesis. Specifically, in NLoS case, we focus on reflected paths due at generic reflection centers located at z-plane. The reflection characteristics of the transmissive channel can be evaluated through the specific knowledge of the local planar geometry associated to the reflection centers.

The use of ray tracing techniques for channel modeling in THz band has been largely adopted, like in [7], where Han *et al.* consider a multi-ray approach with one direct path, and other reflected, scattered, and diffracted paths. According to this approach, the channel model is the combination of several individual narrow sub-bands, each of them with a flat-band response. Assuming N_i narrow sub-bands, and in the case of stationary environment, the channel response in the i-th sub-band is given as

$$h_i\left(\tau\right) = \sum_{n=1}^{N_i}\alpha_{i,n}\delta\left(\tau-\tau_n\right), \tag{18}$$

where $\alpha_{i,n}$ is the frequency-dependent attenuation, and τ_n is the propagation delay of the n-th ray in the multi-ray approach.

From (18), and according to the computations in [7], we can derive the LoS and NLoS channel transfer functions in the case of chirality-affected channel with GOA, respectively as:

$$H_{\mathrm{LoS}}\left(f\right) = H_{\mathrm{Abs}}\left(f\right)H_{\mathrm{Spr}}\left(f\right)e^{-j2\pi f\tau_{\mathrm{LoS}}}, \tag{19}$$

and

$$H_{\mathrm{NLoS}}\left(f\right) = \left[\frac{\nu_c}{4\pi f\left(d_1+d_2\right)}\right]e^{-j2\pi f\tau_{\mathrm{NLoS}}-\frac{1}{2}k(f)(d_1+d_2)}\cdot R\left(f\right), \tag{20}$$

where we assume the NLoS scenario is affected by reflected rays only, through the rough surface reflection loss *i.e.*, $R(f)$.

In (19), H_{Abs} is the transfer function due to the molecular absorption loss, while H_{Spr} is the spreading loss that takes account for the chirality effect through ν_c that is the propagation velocity of the electro-magnetic field in a chiral homogeneous isotropic medium *i.e.*,

$$\nu_c = \frac{c}{n_c}, \tag{21}$$

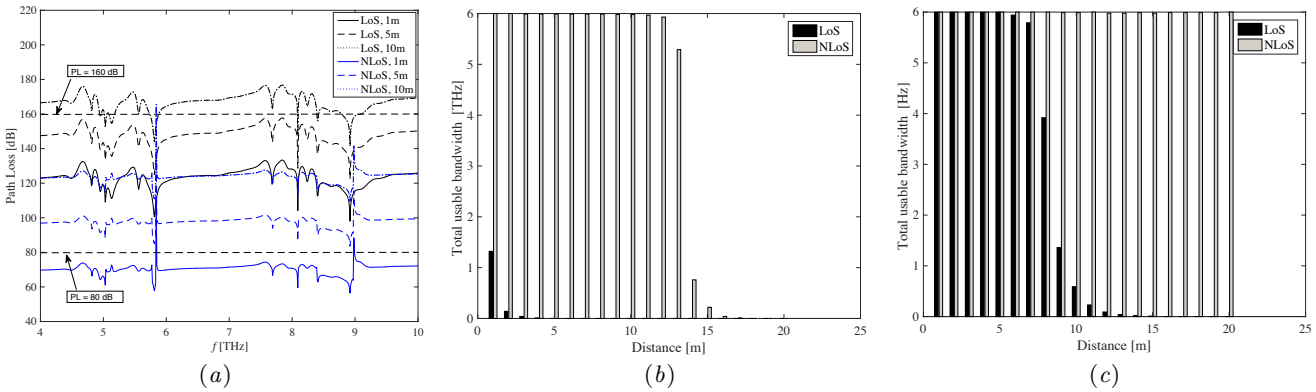
where c is the light propagation speed, and n_c is the refractive index in a chiral medium *i.e.*,

$$n_c = \sqrt{\mu_r\varepsilon_r + \xi_r^2}, \tag{22}$$

with μ_r, ε_r and ξ_r frequency-dependent parameters, according to Figure 1. Finally, under the hypothesis of stationary scenario where the transmitter and the receiver are at a distance d [m], from (19) we obtain the propagation delay for the LoS ray as:

$$\tau_{\mathrm{LoS}} = \frac{d}{\nu_c}. \tag{23}$$

For the NLoS channel transfer function expressed in (20), by assuming d_1 as the distance between the transmitter and a generic reflecting point, and d_2 as the distance between this point and the receiver, we obtain the propagation delay



(a) (b) (c)

Figure 2: Spectral windows in a chiral-affected channel with GOA. (*a*) Path loss, and (*b*) total usage bandwidth for LoS and NLoS propagation in case of a path loss threshold of 120 dB, and (*c*) 160 dB.

of the j-th NLoS ray along the distance $(d_1 + d_2)$, as

$$\tau_{\text{NLoS}} = \frac{d_1 + d_2}{\nu_c}. \tag{24}$$

From the expressions of channel transfer functions in (19) and (20), it is easy to compute the total path loss, as depicted in Figure 2 (*a*) in case of LoS and NLoS propagations, for different distances from transmitter to receiver, and assuming a specific reflecting angle for multi-path. By increasing the distance, the path loss has a higher trend. Moreover, similarly to the results in [9], the LoS propagation (black lines) provides higher values with respect to the NLoS scenario (blue lines). In both LoS and NLoS, the behavior is frequency-dependent, but in LoS propagation the path loss has a smoother trend, with some peaks at 5.8, 8.09 and 8.93 THz. On the other hand, for NLoS propagation, the peaks are well noticeable at 5.8 and 8.93 THz, while on the other frequencies, the trend is on average flat around 70, 100 and 120 dB for LoS at $d = 1$, 5, and 10 m, respectively.

Similarly to the analysis conducted in [9], we aim to characterize the spectral windows of chiral channel transfer functions in case of LoS and NLoS propagation. A spectral window is given by the portion of spectrum below a given path loss threshold. We expect to observe that the path loss peaks caused by the chiral effect create several spectral windows, with different bandwidths in each of them.

In the case of a path loss threshold set to 80 dB, the communication distance is limited for NLoS propagation at lower distance of 1 m, except the two peaks that are above this threshold, and correspond to 5.84 THz and 8.98 THz. According to the values assumed in [9], the threshold of 80 dB corresponds to no gains of transmission and reception antennas, and so to a multi-path propagation model.

In order to identify the spectral windows for LoS propagation, we have to increase the path loss threshold around 120 dB, so that a few windows appear for a distance of 1 m (see curve LoS for $d = 1$ m in Figure 2 (*a*)). However, in this case most of the path loss for LoS propagation is above the threshold, thus providing a reduced usable bandwidth. Figure 2 (*b*) depicts the usable bandwidth versus the distance for the path loss threshold of 120 dB. We notice that the available spectrum in LoS propagation is limited up to 4 m, reaching a maximum at 1.32 THz corresponding to a distance of 1 m. In contrast, the NLoS propagation reaches higher bandwidths, and then it decreases at 17 m where the bandwidth is 0.01 THz. The bandwidth rate in LoS is 75.5 GHz/m, while it reaches 3.90 THz/m in NLoS scenario.

It follows that an increase of the path loss threshold to 160 dB is expected to provide higher values of usable bandwidth in LoS propagation, as depicted in Figure 2 (*c*). Higher path loss thresholds rise from higher antenna gains, and the transmission becomes directional through the LoS path. In this case, the usage bandwidth in LoS propagation reaches higher values than those for the threshold of 120 dB. The lowest value is 0.01 THz for a distance of 15 m, and the average bandwidth rate for LoS propagation is 2.39 THz/m.

On the other side, for NLoS propagation, the usable bandwidth reaches approximately the maximum value of 6 THz for different distances, and then the average rate of the total usable bandwidth is 5.99 THz/m. As a result, we can conclude that within the range (4–10) THz the available bandwidth is almost the entire band, especially for NLoS propagation.

4. CHIRAL CHANNEL CHARACTERIZATION

Following the chirality-affected channel model presented in Section 3, in this section we investigate its main features in the (4–10) THz band. Specifically, we aim to characterize (*i*) the channel capacity, (*ii*) the propagation delay, and (*iii*) the coherence bandwidth.

4.1 Channel capacity and propagation delay

To evaluate the capacity limits in a chiral medium, we refer to the approach adopted in [7], where the received signal has been decomposed as a sum of the sub-bands, each one with a narrow behavior and a flat-band response. The following constraint is adopted:

$$\sum_{i=1}^{N_B} P_i \leq P_{TOT}, \tag{25}$$

where N_B is the total number of sub-bands, P_i is the transmission power in the i-th sub-band, and P_{TOT} is the total transmit power in the (4–10) THz band. Notice that, since the chiral parameter has a frequency-dependent behavior in (4–10) THz band, we consider only this frequency range.

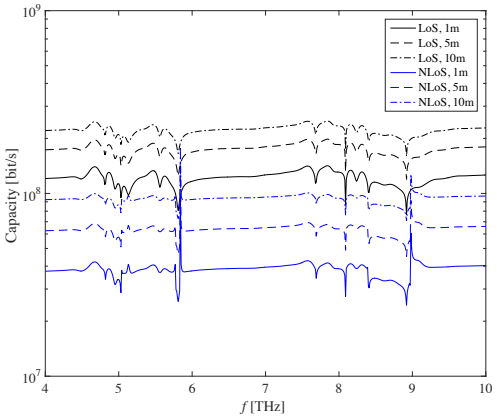


Figure 3: Capacity of a chirality-affected channel with GOA, versus frequency for LoS and NLoS propagation, and different distances.

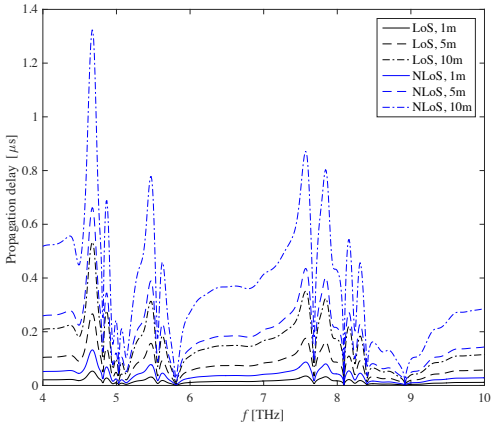

Figure 4: Propagation delay versus frequency in a chirality-affected channel with GOA, for LoS and NLoS propagation, and different distances.

For N_B sub-bands, the capacity can be defined as the sum of the single capacities in each sub-band *i.e.*,

$$C = \sum_{i=1}^{N_B} C_i = \sum_{i=1}^{N_B} \Delta f_i \log\left(1 + \frac{|h_i|^2 P_i}{\Delta f_i S_N(f_i)}\right), \qquad (26)$$

where S_N is the power spectral density of the additive white Gaussian noise, and Δf_i is the sub-band range among two consecutive sub-bands *i.e.*, $\Delta f_i = f_{i+1} - f_i$, assumed as 10 GHz in our simulation results. We assume a flat power profile, that is the total power transmission is uniformly distributed over the entire operative band (*i.e.*, from 4 to 10 THz). Also, we consider a power level of 46 dBm in all the sub-bands *i.e.*, $N_B = 600$.

Figure 3 depicts the chirality-affected channel capacity with GOA in case of LoS and NLoS scenario. We notice that with a reduction of distance, the capacity decreases as well, and also the LoS scenario has a smoother behavior with respect to the frequency, while the NLoS shows an accentuate frequency-dependent trend, with distinguishable peaks at resonance frequencies. Specifically, in LoS, the capacity has an almost flat behavior, with a mean value of 0.22 Gbit/s for $d = 10$ m. Performances get worst in the case of NLoS propagation for $d = 1$ m, where we observe a degradation of capacity at 5.81 and 8.92 THz, corresponding to 25.65 Mbit/s and 24.47 Mbit/s, respectively.

From the expressions in (23) and (24), the propagation delay in LoS and NLoS scenarios is depicted in Figure 4. We observe the frequency-dependent behavior due to the chiral effect, and as expected, performance gets worst when the distance increases. An almost-flat behavior is shown for LoS at short distances (*i.e.*, $d = 1$ m), while a resonant trend appears when increasing the distance, as well as in NLoS scenario due to the longer distances covered. Finally, we observe that the propagation delay both in LoS and NLoS case shows lower values corresponding to 5.81 and 8.92 THz.

4.2 Coherence bandwidth

The root mean square (rms) delay spread is a measure of how dispersive the channel is. It is expressed as [9]:

$$\sigma_i = \sqrt{\overline{\tau_i^2} - \bar{\tau}_i^2}, \qquad (27)$$

where $\overline{\tau_i}$ and $\bar{\tau}_i^2$ are the first and second moments of the instantaneous power-delay profile, respectively. From (27) we can derive information about the coherence bandwidth, defined as the range of frequencies over which the channel correlation exceeds 50%.

In our simulations, we consider two scenarios with a variable number of NLoS reflected rays *i.e.*, (*i*) one, and (*ii*) five, and one direct ray. In both cases, we observe the frequency-dependent behavior as typical of chiral materials exhibiting GOA. In Figure 5 (*a*) we show the coherence bandwidth in the case of one LoS and one NLoS path for different distances. As experienced in [7], higher values are reached for shorter distances. However, we cannot compare our results to others obtained with pre-existing approaches, since the frequency range is not the same.

In our simulations, several peaks appear due to the chirality effects. This can allow tuning the frequency to resonant peaks in order to obtain higher performances. For example, for $d = 1$ m, the minimum value of rms delay is 0.33 ns, corresponding to 8.92 THz. This value corresponds to a symbol rate limited to $0.1/\sigma_i = 0.29$ Gbit/s to avoid inter-symbol interference. Also, in this case, the coherence bandwidth is limited to 0.59 GHz at the frequency peak of 8.92 THz. On the other side, when the distance increases (*i.e.*, $d = 10$ m), the minimum rms delay is 3.6 ns at 8.92 THz. This value provides a symbol rate limited to 27.71 Mbit/s, and the coherence bandwidth equals to 55.43 MHz, still at the same frequency.

Performances get worst in case of multiple reflected paths, as shown in Figure 5 (*b*). For $d = 1$ m the minumum rms is 0.78 ns, which corresponds to a symbol rate of 0.12 Gbit/s and a coherence bandwidth of 0.25 GHz. For higher distances (*i.e.*, $d = 10$ m) the minimum rms is 7.31 ns, corresponding to a coherence bandwidth is 27.3 MHz and symbol rate of 13.6 Mbit/s.

5. CONCLUSIONS

In this paper, we have presented the performance of a chirality-affected channel with GOA, under the hypothesis of LoS and NLoS propagation in the (4–10) THz band. We considered the effects of the relative chiral parameter, assuming a frequency-dependent behavior with resonant peaks

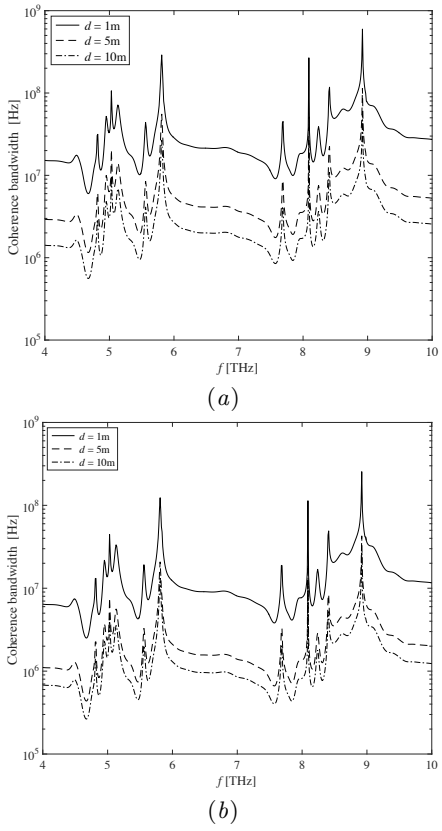

Figure 5: Coherence bandwidth in a chirality-affected channel with GOA, in case of (*a*) one LoS and one NLoS path, an (*b*) one LoS and five NLoS paths.

at specific frequencies. As a result, this affects the channel transfer function, as well as other performances. In particular, we identified the spectral windows that rise from the chiral effect, and the associated usable bandwidths. The spectral windows vary with the distance and the frequency, with corresponding bandwidths up to 6 THz, both in LoS and NLoS propagation. Other results allows to identify specific frequencies that guarantee high performances. As an instance, the rms delay is dependent on the distance and carrier frequency, and reaches minimum values at 8.92 THz, corresponding to higher coherence bandwidths.

We can conclude that this particular material exhibiting GOA can guarantee high performances, especially at lower distances. Also, distance-adaptive and multi-carrier transmissions represent the more appropriate communication techniques that can benefit from the relationship between distance and bandwidth in the range (4–10) THz.
