**Abstract**—Wireless sensor networks are constrained by their energy supply. In order to relief this constraint, scavenging ambient energy from the environment has been considered. However, most existing energy harvesting devices rely on a single energy source, potentially reducing the sensor reliability. In this paper, we present an architecture for multi-source energy harvesting, aimed at low cost and easy integration with existing wireless sensors. Unlike existing architectures, our solution relies on a single power conditioning block. This block is powered by multiple sources, selected through a switch matrix by a dedicated controller. A prototype has been developed, validated and compared with alternative architectures. First results show our architecture benefits for systems using many heterogeneous sources, and highlights improvement possibilities through the addition of MPPT (Maximum Power Point Tracking) circuitry.

## I. INTRODUCTION

Driven by the trend of the Internet of Things (IoT) and the uninterrupted demand for Machine-to-Machine applications, Wireless Sensor Network (WSN) has become an important research area for both academic and industrial worlds. In particular, sensor power efficiency is a particular concern when deploying WSNs, in order to increase their life-cycle and/or their Quality of Service (QoS). Moreover, wireless sensor nodes are heavily cost-constrained. In order to reduce development cost, designers need to rely on flexible and reusable platforms.

Most of the current sensor nodes are powered by batteries, which limits their available energy. In order to save power, most nodes use duty cycling technique: the device is kept in a low power mode most of the time, and only wakes up for a short time when required. A trade-off has to be made between autonomy and QoS, to define the time between two consecutive wake-ups [1]. In order to further increase the QoS of energy-constrained nodes, increasing the available energy with ambient energy harvesting has been considered [2].

A node using energy harvesting classically harvests power from a single energy source, e.g. wind, vibration... A power conditioning block transforms the harvested power in a voltage suitable to charge a battery and power the node. This power conditioning block has to be adapted to the energy source, and can be either a DC/DC voltage converter for continuous current sources such as solar panels or an AC/DC voltage converter for alternative current sources such as wind turbines.

In order to increase the harvested power, one can increase the efficiency of the power conversion or use multiple concurrent energy harvesting devices. In multi-sources energy harvesting devices, the node is powered by a battery that is recharged from multiple heterogeneous sources. To this aim, [3] proposes a circuit which shares a common voltage converter between multiple harvesting sources. Switches are used to sequentially select each source during a time slot that depends on the source capabilities. However, this approach uses dedicated ASIC implementation, which can not be reused, and is too costly for our design constraints. [4] is one of the reference implementations for multi-source energy harvesting sensors. Each energy source has its own DC/DC converter and Maximum Power Point Tracking (MPPT) circuit in order to maximize efficiency. Each source stores its energy in a capacitor, and all capacitors are connected with diodes to form a reservoir capacitor array. Likewise, [5] uses multiple energy harvesting systems with their own converter to charge a common battery. Each converter is only activated when enough power is harvested. This information is sent to the node, enabling the estimation of the harvested power. In a similar manner, [6] uses multiple energy harvesting and storage modules, with plug-and-play detection based on IEEE 1451.4-2004 standard. All these works share the drawback of requiring a dedicated power conditioning circuit by energy harvesting source, thus multiplying the cost and board space required by the solution.

In this paper, we propose a multi-source energy harvesting architecture, which aims for a low cost and flexible implementation with existing energy harvesting devices. The solution relies on a circuit switching between energy sources. Harvested energy is stored in buffers, which are connected to a generic power conditioning block through a switch matrix. A controller is used to decide which energy source should be connected to the power block. Unlike previously described solutions, the proposed architecture uses a single generic power conditioning block to reduce the platform cost. The platform is compatible with multiple energy sources and existing sensor nodes and enables implementation of intelligent control algorithms. To validate the proposed approach, our solution has been implemented on a commercial and deployed platform, and compared with a state-of-the-art system that uses

one power conditioning block for each source.

The rest of the paper is organized as follows. Section II describes the proposed switching system and gives the design choices for each part of the system. Section III presents a prototype implementation of our architecture, its power consumption measurements, and shows its benefits when powering a LoRaWAN-based platform. Finally, this paper is concluded in Section IV.

## II. MULTIPLE SOURCES SWITCHING SYSTEM

### A. System architecture

This section introduces the global design of a modular platform to which multiple energy harvesting devices can be connected. The proposed solution must keep a reasonable cost and must use available Components Off-The-Shelf (COTS) in order to ease industrialization. Moreover, this solution should be flexible enough to be associated with multiple wireless sensor platforms. Fig. 1 shows the block diagram of the proposed multi-source switching system. Each energy harvesting source is connected to a capacitor, which acts as an energy buffer while the source is not in use. Each energy buffer is connected to a central Power Management Integrated Component (PMIC) through an electrically-controlled switch. When an energy buffer is connected to the PMIC, the latter will draw as much current as it can to charge the energy storage and to power the sensor. The energy buffer is thus emptied and another one can be selected through the switch matrix to power the PMIC. A smart controller is used to decide which switch should be closed at each moment.

One of the main limitations of this architecture is that the power path contains two following DC/DC converters, which reduces the overall efficiency of energy conversion. The first one, embedded in the PMIC, is used to transform the input voltage and to charge the battery, while the second, which is part of the sensor node, takes energy from the battery to power the node components. However, this design choice allows to easily associate our system to existing sensor nodes, simply by connecting the PMIC energy storage instead of the node one.

Each function block of the architecture has multiple possible implementations, each one coming with their advantages and

Fig. 1: Multiple source switching system.

limitations. The use of capacitors is the only considered implementation for energy buffers. The following subsections detail the role and possible implementations of each main block: PMIC, switches and controller.

### B. Power conditioning block

The PMIC is the power manager of the platform. Its main role is to transform the incoming energy in a suitable voltage in order to charge the energy storage (super-capacitor or battery). Implementation can be done with discrete components, using separated circuits for voltage conversion, battery charging and Maximum Power Point Tracking (MPPT). Another alternative is to use an Integrated Circuit (IC), which integrates all these functions on a single chip.

Each energy harvesting source has an optimal operating point, called Maximum Power Point (MPP), expressed as the operating voltage  $V_{MPP}$  for which the harvested power is maximized. In order to maximize harvesting efficiency, the converter must keep its input voltage close to  $V_{MPP}$ . As  $V_{MPP}$  is a constant fraction of the harvester open-circuit voltage  $V_{OC}$ , a commonly used MPPT technique is to periodically open the circuit to let the harvester reach its  $V_{OC}$  and to set  $V_{MPP}$  according to the measure of  $V_{OC}$ . The converter switching frequency is then adjusted to match the input voltage to  $V_{MPP}$ .

In the proposed system, this MPPT technique can not be used. Indeed, when the circuit is opened, the input voltage of the PMIC does not reach  $V_{OC}$ , due to the capacitance of the energy buffers, and  $V_{MPP}$  is therefore incorrectly measured. Nevertheless, an external voltage  $V_{MPP}$  can be used and set to an arbitrary reference voltage  $V_{REF}$ . The PMIC will then adapt its DC/DC switching frequency to keep its input voltage close to  $V_{REF}$ . This external control of PMIC can be used by the controller to manage the threshold of the energy buffers.

### C. Switch design

Switching between energy sources is a well-known issue. Power ORing has been used for a long time in applications where power failures are unacceptable [7], such as datacenters. However, these systems are designed for power consumption of several kW, whereas our application uses only a few mW at most. Our architecture also requires switches with no current returns in order not to damage the harvesters.

In our system, an integrated load switch is used, coupled with an ideal diode circuit to avoid reverse current flow. The switch block diagram is shown in Fig. 2. When the output voltage  $V_{OUT}$  is lower than the input voltage  $V_{IN}$ , Q2 PNP transistor will be in blocking state and the FET gate voltage will be 0 V, making it passing. When  $V_{OUT}$  is higher than  $V_{IN}$ , Q2 is saturated, the gate voltage is close to  $V_{OUT}$  and the FET is blocking. The use of two resistors to polarize the PNP transistors creates an additional power consumption. This consumption can be reduced by increasing the resistor values, however the transient response of the circuit will also increase.

Fig. 2: Load switch block diagram and schematic of the ideal diode circuit.

#### D. Controller implementation

In the system, the controller aims at performing the switching process by controlling each switch. Multiple decision algorithms can be implemented depending on the information that the controller could monitor in the system. For example, if the energy levels are known, the controller can allocate a time slot per source that is proportional to its maximum output power. However, as algorithmic considerations are out of the scope of this paper, no information is considered and a passive algorithm is used based on an individual and periodic turn-off of each switch. Each buffer is therefore connected to PMIC during a given duration  $T_{SW}$ .

The only requirement for the controller is that the control signals must be compatible with the selected switches. The controller is an always-on component, thus its power consumption must be reduced to a bare minimum. Although dedicated analogue or digital circuits could lower this power consumption, an ultra low power micro-controller will be used, allowing a good trade-off between power consumption and flexibility.

Indeed, recent micro-controllers usually offer multiple power modes. By keeping the micro-controller in a low power mode and only waking it up when needed, the average power used by the micro-controller can be kept close to its sleep mode power consumption, *i.e.* few  $\mu\text{W}$ . Since the micro-controller functionality is implemented using software, its features can be easily modified, simply by loading a new firmware.

### III. ENERGY BUFFER CAPACITOR SIZING

The input energy buffers are implemented using capacitors. An accurate sizing of these capacitors is required, as an oversized capacitor would increase its leakage current [8], as well as the cost of the solution. On the other hand, an undersized capacitor would be too quickly charged by its energy harvester, leading to energy waste. In the proposed architecture, the size of the input energy buffers depends on both voltage and current provided by the harvesting device, but it also depends on the switching process (*i.e.* number of

harvesting devices, period  $T_{SW}$  between two decisions, and decision algorithm).

Let  $C_{BUF}$  be the buffer capacitance and  $V_{BUF}$  its voltage, the current  $I_{BUF}$  is given by:

$$I_{BUF} = C_{BUF} \frac{dV_{BUF}}{dt}. \quad (1)$$

The use of a solar panel is considered, which can provide up to  $V_{OC}$  Volts,  $I_{MAX}$  mA and has its MPP at  $V_{MPP} = \alpha * V_{OC}$ . At initial conditions, energy buffer is supposed to be empty with a voltage down to  $V_{REF}$ . During charging state, once the voltage  $V_{BUF}$  reaches  $V_{MPP}$ , the power provided by the panel starts to decline. The energy buffer is thus considered to be "charged" when its voltage rises above the  $V_{MPP}$  voltage of its harvester. The time  $t_{CH}$  required to charge the capacitor up to  $V_{MPP}$  is expressed by:

$$t_{CH} = C_{BUF} \frac{\alpha * V_{OC} - V_{REF}}{I_{BUF}}. \quad (2)$$

As the current  $I_{BUF}$  depends on its voltage, the worst case is considered with  $I_{BUF} = I_{MAX}$ . Over-sizing the current at  $I_{MAX}$  leads to a shorter charging time, and thus a bigger capacitance.

The capacitance also depends on the switching process between multiple harvesters. Considering a decision algorithm with a periodic switch between the  $N$  sources, one buffer is connected to PMIC during  $T_{SW}$ , while being in charging state during  $(N-1)T_{SW}$ . Therefore, to avoid overcharging the energy buffers in such a scheme,  $t_{CH}$  should be greater than or equal to  $(N-1)T_{SW}$ . With this constraint, the minimal energy buffer capacitance  $C_{BUF}$  can be computed by:

$$C_{BUF} \geq \frac{T_{SW} * (N-1) * I_{MAX}}{\alpha * V_{OC} - V_{REF}}. \quad (3)$$

Finally, a safety margin is used to prevent capacitance variations, which can occur according to ambient temperature, input voltage or chosen technology, and which can change over time. This margin can be analytically derived from the capacitor specifications.

This expression has been validated through electrical simulations on LTSpice, using a solar panel model as the energy source. For different capacitances and various illumination conditions, the charging time  $t_{CH Sim}$  from  $V_{REF} = 1.8 \text{ V}$  to  $V_{MPP}$  is simulated, and compared with the theoretical time  $t_{CH Calc}$  calculated using (2). Simulation results, shown in Table I, show that our model deviates from simulation when illuminance is low. This difference leads to oversizing the energy buffers, slightly increasing the circuit cost and leakage currents. However, it enables a simplified and sped-up capacitor sizing for each system configuration.

### IV. PROTOTYPING AND MEASUREMENTS

#### A. Implementation

A prototype of the system presented in the previous section was developed. This implementation aims for functional validation of the platform. The chosen PMIC is a SPV1050 from ST microelectronics, due to its wide input voltage range. This

$I_{ll}$ [lux]	$C_{BUF}$ [ $\mu F$ ]	$t_{CH\ Sim}$ [s]	$t_{CH\ Calc}$ [s]	$\Delta t_{CH}$ [%]
100	10	0.262	0.331	26.3
100	100	2.261	3.304	26.0
100	1000	26.214	32.996	25.9

200	100	1.431	1.755	22.7
200	1000	14.306	17.529	22.5
500	10	0.064	0.074	16.4
500	100	0.636	0.739	16.3
500	1000	6.357	7.374	16.0
1000	10	0.034	0.036	5.3
1000	100	0.342	0.361	5.6
1000	1000	3.418	3.641	6.5

TABLE I: Comparison between  $t_{CHCalc}$  and  $t_{CHSim}$ .

IC integrates a resistor divider based MPPT circuit. Moreover, an external voltage can be applied to manually set the target operating point. If this voltage is not set, the PMIC uses MPPT circuitry, as described before.

The implemented load switch is a SiP32431 from Vishay, coupled with the ideal diode circuit described in the previous section. Due to its input voltage limitations, this circuit can only be used for energy harvesting sources providing voltage between 1.1 V and 5.5 V. For different voltages, another load switch should be used.

The controller is implemented using an MSP430FR5969 micro-controller from Texas Instruments. Its extensive power modes enable to lower the power consumption of the controller to few  $\mu W$ . Its flexible clocking trees enable the use of many peripherals while being in low power mode. In our implementation, to avoid adding an external Digital-to-Analogue Converter (DAC), an internal timer is used as a Pulse Width Modulation signal, averaged through a low-path RC filter to provide the PMIC its  $V_{REF}$  voltage.  $V_{REF}$  is set to 1.1 V at minimum, to keep the energy sources voltages in the SiP32421 voltage range. A TPS60210 charge pump with ultra-low quiescent current is used to power the MSP430 with a constant 3.3 V voltage, attenuating the battery voltage variations.

### B. Energy consumption overhead

One of the main design goals for the harvester control system is to have a low power consumption in order to not disturb the node energy harvesting capabilities. Thus, we measured the system power consumption to ensure that the power consumption overhead of the proposed system is kept low. Power consumption of each block has been separately measured, and can be directly compared with the input power. The results are displayed in Fig. 3.

1) *PMIC power consumption*: The PMIC includes some control electronics, and thus has a quiescent current consumption. To measure only the power consumption overhead of our solution and not the overall conversion efficiency, the power losses due to the PMIC voltage conversion are not taken in account. The quiescent power losses are shown in Fig. 3a.

2) *Load switch power losses*: In order to measure the power losses  $P_{LOSS}$  of the load switch, the output power of the switch is subtracted to its input power  $P_{IN}$ . Measurements

have been performed with three different load resistors  $R_L$ , for different input voltages  $V_{IN}$ . A measurement campaign has also been run while varying the voltage of the switch output, in order to measure its reverse leakage power losses  $P_{LOSS_R}$ .

Fig. 3b shows the raw power losses induced by the proposed load switch. In all cases, the power consumption is similar and gives a maximum loss of 74  $\mu W$  for 5.5 V f. As most power losses come from the ideal diode circuit resistors, these losses are voltage dependent, and different loads have no impact. However, this also means that the power consumption overhead of the switch is proportionally higher when a lower current is flowing through, as shown in Fig. 3c. In our use-case, the current flowing through the switch is reduced when the energy buffer voltage  $V_{BUF}$  is close to the reference voltage  $V_{REF}$ , *i.e.* when the buffer is nearly depleted.

Moreover, the switches have a reverse power leakage. These losses are due to the ideal diode resistors, and thus are close to the losses of a passing switch, as shown in Fig. 3d. Adding too many energy harvesting sources has a negative impact on total harvested power, as it increases the total reverse leakage power of the switches. In the case of a system with  $N$  energy harvesting devices, the reverse power losses are equal to  $(N - 1) \times P_{LOSS_R}(V)$ .

However, these power losses only affect the currently selected energy harvesting source, which provides current to the PMIC. When the switch is in blocking mode, the other sources are charging their respective energy buffer. Thus, the only power losses that affect them are the leakage current of the energy buffer and the power consumption of the SiP32421 load switch. These power losses are in order of  $\mu W$ , as can be seen in Fig. 3e.

3) *Controller power consumption*: The MSP-EXP430FR5969 development platform provides an embedded energy measurement tool, enabling real-time measurement of the controller power consumption. In order to take into account the power drawn by the controller charge pump, we powered our development board from the charge pump, and powered this charge pump from the integrated debugger 3.6 V power supply. The charge pump is set in low-power mode, so that its quiescent current consumption is minimized. The State-of-Charge (SoC) of the main energy storage is measured with an external ADC with high input impedance through a resistor divider.

The controller implements a simple decision algorithm, which alternatively closes the switches each  $T_{SW} = 1$  s. It also implements a simple power manager, which measures the main energy storage SoC and commands the sensor node to transmit a packet if the storage is charged. Therefore, the more energy is harvested, the lower the period between two transmissions  $T_{PTX}$  will be.

Fig. 3f illustrates the power consumption of the controller on a 10 second period. To get the average power consumption of the full circuit, a 5 minute measurement has been run. The mean power consumption was 334  $\mu W$  for a current of 92  $\mu A$ . The power losses induced by the controller are relatively high,

Fig. 3: Power consumption overhead of the platform.

and mainly come from the ADC measurements required by the power manager. If the switch system is implemented without the power manager, the power consumption of the controller decreases at  $185 \mu\text{W}$  for a current of  $51 \mu\text{A}$ .

### C. System validation

1) *Test set-up*: Our system is used to power a wireless sensor developed by Wi6labs [9]. This platform is built around a STM32 micro-controller from STmicroelectronics, and uses the LoRaWAN protocol for communications. This choice eases the estimation of the power consumption of the node. Indeed, as the LoRaWAN network has a star topology, an end-device does not have to route any message and its power consumption does not depend from the other nodes behavior.

Voltage generators are used to emulate sources. The first source is set at 4.2 V, while the second is set between 1.5 V, 3.1 V or 3.7 V. Both sources are limited to 1 mA in order to simulate low power sources. As the sources are fixed, different measurements can be performed in a consistent set-up, without influence from the environment. However, these sources are still oversized compared to real energy sources. As the power provided by real sources would be lower, the power consumption overhead of the circuit would have a higher impact on the harvested energy.

Even if these energy sources are oversized, compared to low power provided by real energy sources, the use of deterministic sources allows an accurate characterization of the proposed system. Different measurements can be performed in a consistent set-up, without being affected by the environment. The input energy buffers used are arbitrarily chosen and have respectively a  $4700 \mu\text{F}$  and  $1000 \mu\text{F}$  capacitance, while

the energy storage is a capacitor array with a  $34.7 \text{ mF}$  total capacitance.

2) *Measurements*: The realized prototype is functional and shows that the system is able to self-start. Functionality of the controller has also been validated using a simple switch algorithm. In order to compare our proposal against alternatives, a prototype close to the state-of-the-art parallel architectures has been set-up. In this prototype, two PMIC SPV1050 are used in parallel, and charge the same energy storage. Both PMIC include MPPT and battery protection. The following situations are evaluated:

- $S_{1/2}$ : Source 1/2 only, with MPPT
- $D$ : Source 1 and 2 connected to a single PMIC through ideal diode circuit, without MPPT
- $D_{MPPT}$ : Source 1 and 2 connected to a single PMIC through ideal diode circuit, with MPPT
- $Switch_{1V1/3V}$ : Periodic switch ( $T_{SW} = 1 \text{ s}$ ) with PMIC  $V_{REF}$  set to 1.1 V/3.0 V
- $Parallel$ : Parallel architecture - two PMIC directly connected to the battery, with MPPT.

For all situations, the period  $T_{PTX}$  between two consecutive LoRa packet transmissions is measured ten times. The average value  $\overline{T_{PTX}}$  is then computed. These results are shown in Fig. 4.

3) *Discussion*: The situation  $D$  performs significantly worse than single-source situations, while  $D_{MPPT}$  performs better. This is due to the lack of any MPPT in situation  $D$ , and shows the impact of MPPT. However,  $D_{MPPT}$  is a naive implementation, and is not efficient if the two voltages are too different. When the MPPT circuit measures  $V_{OC}$ , it will measure the highest voltage in all sources, and set its  $V_{MPP}$

Fig. 4: Period in s between two LoRa TX depending on situation and  $S_2$  voltage.

accordingly. Thus, a source with a lower voltage will operate far from its MPP, or will not provide power even if its voltage is smaller than the measured  $V_{MPP}$ .

Our solution is hindered by the lack of MPPT. By setting  $V_{REF}$  too low, as in situation  $Switch_{1V1}$ , the sources operate far from their optimal power point, and provide less energy. Alternatively, rising  $V_{REF}$  too high may render some sources useless. Indeed, if  $S_1$  is set at 4.2 V, rising  $V_{REF}$  to 3 V brings the converter operating point closer to the source MPP. But, if the second source voltage is smaller than  $V_{REF}$ , no current will be drawn, and the source will not be used at all. However, if  $V_{REF}$  is close to both sources MPP, such as situation  $Switch_{3V}$  with  $S_2$  set at 3.7 V, our solution performs correctly. This demonstrates the potential of our solution, when the sources operate close to their MPP.

The energy buffer size has also an impact on the system: an oversized buffer takes more time to charge, and the energy source takes a longer time to reach its  $V_{MPP}$ . In order to maximize harvesting efficiency, decision algorithms should be designed so that the sources operate near their MPP. Possible solutions include setting  $V_{REF}$  from a DAC and adapt its value according to the selected source, or adding a full-featured MPPT circuit between a source and its energy buffer.

Cost was a primary concern when designing our system. Table II shows the cost associated with a state-of-the-art parallel architecture and our switching architecture. Only active components are taken in account. Prices are obtained from standard distributors for 100 pieces of each component. Ideal diode cost is estimated.  $N$  designates the number of harvesters in the system. Our system becomes cost effective for  $N \geq 3$ , which makes it interesting for systems using a large number of energy sources.

Component		Switching Arch.		Parallel Arch.	
Name	Unit Price	Count	Price	Count	Cost
SPV1050	\$2.21	1	\$2.21	$N$	$\$N \times 2.21$
MSP430	\$0.70	1	\$0.70	0	\$0
TPS60210	\$1.47	1	\$1.47	0	\$0
SiP32431	\$0.28	$N$	$\$N \times 0.28$	0	\$0
Ideal diode	\$0.30	$N$	$\$N \times 0.30$	0	\$0
Total		1	$\$(4.38 + N \times 0.58)$	1	$\$N \times 2.21$

TABLE II: Cost breakdown of the solution.

## V. CONCLUSION

This paper describes a multi-source energy harvesting architecture, where multiple energy sources are multiplexed into a single PMIC through a switch matrix. The use of a single voltage converter enables to lower the cost of the solution. The system was validated with a LoRa wireless sensor platform and its power consumption overhead was measured. Measurements show that our solution can efficiently power a node from multiple energy sources, when all sources operate close to their MPP. Future work will focus on adding ultra low power MPPT circuits to keep each source close to its MPP, thus maximizing harvesting efficiency for each source, while not adding too much cost. The simplification of the controller implementation will also lower the cost of the platform.
