## ABSTRACT

We introduce **Approximate Unrolling**, a loop optimization that reduces execution time and energy consumption, exploiting the existence of code regions that can endure some degree of approximation while still producing acceptable results. This work focuses on a specific kind of forgiving region: counted loops that map a given functions over the elements of an array. **Approximate Unrolling** transforms loops in a similar way **Loop Unrolling** does. However, unlike its exact counterpart, our optimization does not unroll loops by adding exact copies of the loop's body. Instead, it adds interpolations.

We describe our experimental implementation of **Approximate Unrolling** in the Server (C2) Compiler of the OpenJDK Hotspot JVM. The choice to implement our technique directly in the compiler reduced Phase Order problems and transformation overhead. It also proved that our technique could actually improve the performance of a production-ready compiler. Using our modified version of the compiler, we perform several experiments showing that **Approximate Unrolling** is able reduce execution time and energy consumption of the generated code by a factor of 50% with minimal accuracy losses.

## Keywords

approximate computing; compiler optimizations; loop unrolling

## 1. INTRODUCTION

Approximate computing exploits the fact that some computations can be made less precise and still produce good results in order to reduce execution times and energy consumption [25]. Previous works in the field have proven that when small reductions in accuracy are acceptable, significant improvements in execution times and energy consumption can be achieved [41]. Opportunities for approximation arise all along the stack and researchers have proposed techniques to approximate in both hardware and software.

Hardware-oriented approximation techniques have proposed components with approximation capabilities, such as FPUs [38], adders [16, 33] and memories [10, 20]. They also exploit the inherent non-determinism of existing hardware as sensors [21] and wireless adapters [32] and some even expose it to developers [7, 36]. On the software-oriented side of approximate computing, the proposed techniques modify existing algorithms automatically [34, 24, 28] or provides support for programming with approximation via language design [23, 30], frameworks [6, 7] and compilers [4].

In this work we describe a loop optimization, namely **Approximate Unrolling**, that uses the ideas of approximate computing to reduce execution times and energy consumption of loops mapping values to arrays. These loops are commonly encountered in programs that process signals and that exploit heuristics. In addition, these loops account for a large part of the computation, e.g., the loops that we analyze in our case study are executed millions of times in a few seconds. Consequently, saving resources on these loops can have a major impact on the program's consumption, as long as the results remain acceptable for the users.

The key insight of **Approximate Unrolling** relies on the following observation: data such as time series, sound, video and 3D Meshes are frequently represented as arrays where contiguous slots contain similar values. As consequence of this neighboring similarity, computations producing this data are usually locally smooth functions. In other words, computations producing or modifying nearby array values representing these kinds of data frequently yield similar results.

Our technique exploits this observation by searching for loops where computations results are assigned to contiguous array slots in each iteration. Then, we substitute some of these computations by inexpensive interpolations of the values assigned to nearby array values. In exchange for this loss in accuracy, we obtain a faster and less energy consuming loop.

To substitute iterations, **Approximate Unrolling** works in a similar way as Loop Unrolling. Yet, instead of unrolling by adding exact copies of the loop's body, it adds code that interpolates the computations performed by the original loop, creating approximate iterations that interpolate some mappings. The code of the approximate iteration is minimal, thus reducing execution time and energy consumption of the whole loop.

We have modified the OpenJDK Java Server (C2) compiler to include **Approximate Unrolling** as a machine-independent optimization. All machine-independent opti-

mizations (and therefore ours as well) reshape the C2’s internal representation of a program to obtain an optimized version of the same program. **Approximate Unrolling** performs a static analysis over the C2’s Internal Representation (IR) to find loops matching certain pattern. Then, those loops are transformed by reshaping the C2’s IR.

Our initial implementation of **Approximate Unrolling** relied on source code and bytecode transformations. Unfortunately this led to a phase ordering problem, breaking other compiler optimizations and failing to gain the expected performance. We then decided to implement the optimization directly in the compiler, allowing us to respect the existing phase order. This also reduced the overhead since we had a direct access to the internal representations provided by the compiler. In addition, this gives us guarantees about the fact that **Approximate Unrolling** can actually has an impact on the performance of a highly optimized code created by production-ready compiler.

Our experiments shows that **Approximate Unrolling** is able to reduce the execution time and energy consumption of the x86 code generated around 50% to 80% while reducing the accuracy to acceptable levels.

The contributions of this work are:

- **Approximate Unrolling**, an approximate loop transformation
- A formal specification of loops targeted by **Approximate Unrolling** and of the behavior of the transformation
- An efficient implementation of **Approximate Unrolling** inside the OpenJDK Hotspot VM.
- An empirical assessment of the effectiveness of **Approximate Unrolling** to trade accuracy for time and energy savings.

The rest of the paper is organized as follows, in section 2 we describe our optimization and its scope. We then detail our implementation in section 3 and our evaluation in section 4. Section 6 describes how **Approximate Unrolling** compares with other approximate computing techniques and finally section 7 concludes.

## 2. APPROXIMATE UNROLLING

In this section we describe the main contribution of our paper, which is the **Approximate Unrolling** approximate loop optimization. We first introduce the intuition of the optimization using the toy example of listing 1. Afterwards, we formally characterize the loops that **Approximate Unrolling** can target. Finally, we introduce the formal semantics governing the proposed optimization.

### 2.1 Illustrating Example

**Approximate Unrolling** creates an alternative version of the loop by unrolling it with operations that interpolate the computations performed in the loop’s original body. We propose two variants: linear or nearest neighbor interpolations. Both are supported by our implementation, which is able to choose one single transformation for each loop.

The loop of listing 1 will serve to illustrate both transformations. The loop maps a sine wave into an array and belongs to a music synthesizer. Conceptually, the example

loop transformed by **Approximate Unrolling** using linear interpolation looks like the one in listing 2, while the same loop approximated with nearest neighbor looks like the one in listing 3. The output of these loops is depicted in figure 1.

```
@Approximate double A[] = new double[N];
double stride = Math.PI * 2 / N;
for ( int i = 0; i < N; i++ )
    A[i] = Math.sin(i * stride);
```

Listing 1: A loop mapping a sine wave into an array

```
double A[] = new double[N];
double stride = Math.PI * 2 / N;
A[0] = Math.sin(0);
for ( int i = 2; i < N; i += 2 ) {
    A[i] = Math.sin(i * stride);
    A[i - 1] = (A[i] + A[i-2]) * 0.5f; }
if ( i == N)A[i-1] = Math.sin((i - 1) *
    stride);
```

Listing 2: The loop of listing 1, transformed by Approximate Unrolling using linear interpolation

```
double A[] = new double[N];
double stride = Math.PI * 2 / N;
for ( int i = 0; i < N; i += 2 ) {
    A[i] = Math.sin(i * stride);
    A[i + 1] = A[i]; }
```

Listing 3: The loop of listing 1, transformed using nearest neighbor interpolation

Figure 1: Sine waves generated by the motivation examples. The upper wave is generated by the loop of listing 1, while the middle and lower ones are generated by loops of listing 2 and 3, respectively.

As the modified loop of listing 2 shows, when using linear interpolation, **Approximate Unrolling** adds code to the loop’s body that interpolates the computations of the odd iterations as the mean of the even ones (the computations of iteration one are interpolated using the results of iterations zero and two, computations of iteration three are interpolated using the results of two and four and so on). Initially, **Approximate Unrolling** peels iteration zero of the loop. Then, it modifies the initialization and updates the statements to double the increment of the loop’s counter variable. As result of this, if the original loop performed an even number of iterations, the last iteration would not be performed. To cover for this case, **Approximate Unrolling** also peels the last iteration.

The procedure with nearest neighbor is quite similar, **Approximate Unrolling** only modifies the update statement to double the increment of the loop’s counter variable. It also adds code with the nearest neighbor interpolation at the end of the loop’s body.

$i, n \in \mathbb{Z}$      $B \in \{\text{expression}\}$      $\llbracket B \rrbracket \in \{\text{true}, \text{false}\}$      $t\_body = C$      $I_0, C \subset \{\text{statement}\}$      $\xi = \langle B, i := i + n, C \rangle$

**Figure 2: Common definitions and rules used by both linear and nearest neighbor transformations**

$$\begin{array}{c} \text{For}_N \frac{}{(For_N(I_0, B, i := i + n) C, \sigma) \rightarrow (I_0; \text{Ex}_N(\xi), \sigma)} \quad \text{Ex}_N \frac{}{(\text{Ex}_N(\xi), \sigma) \rightarrow (\text{if } (B) C; \text{Aprx}_N(\xi), \text{ else SKIP}, \sigma)} \\ \text{Aprx}_N \frac{}{(\text{Aprx}_N(\xi), C, \sigma) \rightarrow (i := i + n; \text{if } (B) a[i] := a[i - 1]; i := i + n; \text{Ex}_N(\xi) \text{ else SKIP}, \sigma)} \end{array}$$

**Figure 4: Small step SOS of Approximate Unrolling using nearest neighbor**

$\langle \text{target\_for} \rangle ::= \text{'for' } \langle \text{' } \langle \text{expression} \rangle \text{' } \langle \text{expression} \rangle \text{' } \langle \text{update\_expression} \rangle \text{' } \langle \text{t\_body} \rangle$   
 $\langle \text{update\_expr} \rangle ::= \langle \text{identifier} \rangle \text{' += ' } \langle \text{integer} \rangle$   
 $\langle \text{t\_body} \rangle ::= \langle \text{' } \langle \text{statement} \rangle \langle \text{array\_assign} \rangle \langle \text{statement} \rangle \text{' } \langle \text{array\_assign} \rangle ::= \langle \text{expression} \rangle \text{' [ ' } \langle \text{index\_expr} \rangle \text{' ] ' } \langle \text{expression} \rangle$   
 $\langle \text{index\_expr} \rangle ::= \langle \text{expression} \rangle$

**Grammar 1: Grammar of for loops targeted by Approximate Unrolling**

## 2.2 Target Loops

Our optimization targets the subset of Java for loops that (i) have an update expression that increments or decrements a variable by a constant value (ii) contain an array assignment inside its body (iii) the indexing expression of the array assignment is value-dependent on the loop's update expression.

We now use Backus-Naur form to formalize the syntax of the loops abiding to (i) and (ii), while (iii) is formalized using data flow equations. For the sake of simplicity, we only show the case in which the variable is being incremented. It should not be difficult for the reader to derive these rules for the case in which the variable is being decremented.

Grammar 1 shows the BNF rules defining the kind of loops **Approximate Unrolling** can target. In the grammar, the non-terminal rules  $\langle \text{expression} \rangle$ ,  $\langle \text{identifier} \rangle$ ,  $\langle \text{integer} \rangle$  and  $\langle \text{statement} \rangle$ , define the Java expressions, identifiers, inte-

ger literals and statements respectively. Rule  $\langle \text{target\_for} \rangle$  describes the loops targeted by **Approximate Unrolling**. The rule introduces two other non-terminals. The first non-terminal:  $\langle \text{update\_expr} \rangle$  describes the expected update expression or the loop, consisting in a variable being incremented by a literal value, while  $\langle \text{t\_body} \rangle$  describes a list of statements containing at least one array assignment, which are described using the  $\langle \text{array\_assign} \rangle$  non-terminal.

The  $\langle \text{index\_expr} \rangle$  rule reduces to a Java expression and facilitates the formalization of condition (iii), which we do as follow: let  $L$  be a loop conforming to Grammar 1, let  $A_L$  be the set of expressions inside the body of  $L$  conforming to  $\langle \text{index\_expr} \rangle$  and let  $U_L$  represent the update expressions conforming to  $\langle \text{update\_expr} \rangle$  for the same loop  $L$ . Also, let  $REACH(X)$  be the *reaching definitions set* [13] data-flow equation for a given expression. We say (iii) holds if:

$$\exists a_i \in A_L : U_L \in REACH(a_i) \quad (1)$$

To recapitulate, loops targeted by **Approximate Unrolling** are those loops conforming to grammar 1 for which equation (1) holds.

As example, the loop of listing 1, conforms to grammar 1. The rule  $\langle \text{update\_expr} \rangle$  reduces to 'i++', while rule  $\langle \text{t\_body} \rangle$  reduces to a single  $\langle \text{array\_assign} \rangle$  statement: 'A[i] =...'. Finally,  $\langle \text{index\_expr} \rangle$  reduces to 'i'. Is also true that equation (1) holds for the loop. There,  $A_L = \{\text{'i'}\}$ ,  $U_L = \text{'i++'}$  and  $REACH(\text{'i'}) = U_L$ .

## 2.3 Transformation's Operational Semantics

Figures 3 and 4 show the operational semantics for **Approximate Unrolling** in small step operational style. The rules in figure 3 specify the transformations for the linear interpolation, while the rules in 4 the transformations for the nearest neighbor. Finally, figure 2 provides a group of

rules and definitions used to define the semantics of both transformations. As with the syntactic part, to keep the rules simple, we only describe the case in which the variable is incremented.

As defined in Figure 2,  $B$  is a boolean Java expression and  $I_0$ ,  $C$  are sets of Java statements.  $I_0$  represents the initialization statements, while  $C$  the loop’s body. The tuple  $\xi$  is a syntactical sugar to make the rules more compact. We use the common definitions for rules **SKIP**, **ASSIGNMENT**, **SEQUENCE** and **IF**.

### 2.3.1 Rules For the Linear Transformation

In this subsection we describe the semantic rules of the linear transformation as follows:

**For<sub>L</sub>**. The *For<sub>L</sub>* rule interpret a loop using linear interpolation. The rule reduces to the interpretation of the loop’s initialization statement  $I_0$  and if predicate  $B$  holds, rule *Pre* is interpreted.

**Pre**. As shown in listing 1 the loops approximated using linear interpolation have iteration zero peeled. This rule represents such initial peeled iteration. It reduces to the interpretation of the loop’s body once, without any modifications. Then, the exact part of the loop (described by rule *Ext<sub>L</sub>*) is called.

**Ext<sub>L</sub>**. This rule represents one loop’s exact iteration. The odd iteration is skipped by doubling the incrementing of the counter variable ( $i := i + 2n$ ), then if predicate  $B$  still holds, an exact iteration of the loop is executed. Next, the code approximating intermediate values is called in rule *Apr<sub>L</sub>*.

**Apr<sub>L</sub>**. Approximate the value of odd arrays slots. The approximation is found as the mean of the previous and following values of the approximate slot, the value of the even iteration array slot is calculated as:

$$a[i - n] := (a[i] + a[i - 2n]) * 0.5.$$

Notice that the counter’s variable  $i$  was incremented twice to skip the approximate iteration in the exact one, therefore the odd slot must be accessed now using index  $i - n$  and the previous even slot using index  $i - 2n$ .

**Post** As the initial iteration is peeled and the counter’s variable value is doubled to unroll the loop, when the amount of iterations in the original loop is an even number, the last iteration of the loop is not executed. To solve this, one last iteration is peeled and appended after the loop.

### 2.3.2 Rules For the Nearest Neighbor

Similarly to what we did for the linear transformation, in this section we describe the semantic rules for the nearest neighbor transformation.

**For<sub>N</sub>**. The *For<sub>N</sub>* rule transforms a loop using nearest neighbor interpolation. The rule can be reduced to the execution of the initialization statements  $I_0$ , followed by the execution of *Ex<sub>N</sub>*.

**Ex<sub>N</sub>** This rule executes an exact iteration of the loop if the predicate  $B$  holds, then it calls *Apr<sub>N</sub>*.

**Apr<sub>N</sub>** The rule increment the counter variable, approximates one array slot by setting its value equal to the one calculated before and then it increments the variable again. Finally *Ex<sub>N</sub>* is called. Unlike linear interpolation, the rule is supposed to approximate the value of the array assigned in the even iteration.

## 3. IMPLEMENTATION

This section describes our experimental implementation of **Approximate Unrolling** in the C2 compiler of Hostpot.

The Hostpot V.M. is used by billions of devices today. It come packed with two compilers: C1 (or Client) and C2 (or Server). When a program starts to run, the bytecode is interpreted. The segments of code executed frequently (hot), are compiled using C1 or C2, depending on how ‘hot’ the code is. C2 is slower, but creates faster code.

We choose to implement **Approximate Unrolling** directly in the C2 because our initial source code manipulation techniques failed to improve performance as they forbid other optimizations. The fact that the optimization order influences the quality of the code (a. k. a Phase Ordering problem) is a well known issue[17] in compiler design. Implementing **Approximate Unrolling** in the compiler also reduced the implementation’s overhead as otherwise we would have need to create data structures such as the value dependency graph already provided by the compiler. Also, implementing the optimization in the C2, we provide support for other JVM languages such as Scala. Finally, this implementation showed that we could improve the performance of a production-ready compiler.

### 3.1 Approach overview

**Approximate Unrolling** is a machine independent optimization. This kind of optimization operates by reshaping the *Ideal Graph*, which is the internal representation (IR) of the C2 compiler.

In a nutshell, our implementation for nearest neighbor works as follows: the *Ideal Graph* contains nodes representing operations very close to assembler instructions. Nodes are linked by edges representing data dependencies. In the graph, there is a node type called **Store** that represents a storage to memory. Our transformation is performed after the compiler performs the ‘regular’ Loop Unrolling. During the unrolling, each node in the loop’s body gets duplicated, resulting in one extra node for each unrolled iteration. Let us consider **StoreA**, a node representing a value storage into memory owned by an array. Before the unrolling there is only one node, **StoreA**, after the unrolling there are node, **StoreA** and **StoreB**. If we find nodes like **StoreA** and **StoreB** in a loop body, we disconnect one of the **Store** nodes (say **StoreA**) of all its value-dependencies and connect to the value-dependencies of the other (say **StoreB**), resulting in both **Store** storing the same value in two different array slots. Then, we delete of all nodes on which **StoreA** was originally value-dependent, removing most computations of one iteration. For linear interpolation the process is very similar, the only difference is that some nodes are added and connected to **StoreA** to perform the mean calculation.

During the rest of the section we expand on this process, we first describe the internal representation of the Compiler, the *Ideal Graph*, then we go in details of our implementation and exemplify it using a toy loop. Our modified version of the Hostpot JVM is available on the webpage of the **Approximate Unrolling** project <sup>1</sup>

### 3.2 The Ideal Graph

The C2’s internal representation is called the *Ideal Graph* (IG) [12]. It is a *Program Dependency Graph* [14]. All C2’s

<sup>1</sup><https://github.com/approxunrollteam>

machine independent optimizations work by reshaping this graph.

In the *Ideal Graph* (IG), nodes are objects and hold metadata used by the compiler to perform optimizations. Nodes in this graph represent instructions as close as possible to assembler language (i.e. `AddI` for integer addition and `MulF` for float multiplication). The IG metamodel has nearly 380 types of nodes. We deal with five of them: `Store`, `CountedLoop`, `Phi`, `Add` and `Mul`.

`Store` nodes represent storages into memory. They contain metadata indicating the type of variable holding the memory being written, making it easy to identify `Store` nodes writing to arrays. The *Ideal Graph* is in Static Single Assignment (SSA) form and the `Phi` nodes represent the  $\phi$  functions of the SSA. `CountedLoop` represents the first node of all the loops that **Approximate Unrolling** can target. The `CountedLoop` type contains two important metadata for our implementation: a list of all nodes representing the loop’s body instructions and a list with all nodes of the update expression. Finally `Add` and `Mul` nodes represents the addition and multiplication operations.

Nodes in the IG are connected by *control edges* and *data edges*. Yet, *data edges* are the most important ones for our implementation, and we will refer to this kind of node exclusively, unless noted otherwise. *Data edges* describe value dependencies, therefore the IG is also a directed *Value Dependency Graph* [3]. If a node *B* receives a *data edge* from a node *A*, it depends on the value produced by *A*. Edges are pointers to other nodes and contain no information. Edges are stored in nodes as a list of pointers. The edge’s position in the list usually matters. For example, in `Div` (division) nodes the edge in slot 1 points to the dividend and the edge in slot 2 points to the divisor.

The `Store` requires a memory address and a value to be stored in the address. The memory edge  $e_M$  is stored at index 2 and the value edge  $e_V$  at index 3. Edge  $e_M$  links the `Store` with the node computing the memory address where the value is being written, while  $e_V$  links the `Store` with the node producing the value to write.

Let us consider the very simple example of listing 4. The resulting IG for this loop is shown in figure 5. In the figure, the `StoreI` represents the assignment to `A[i]`, the `MulI` node represents the `i*i` expression. The address is resolved by the nodes in the Cluster A (containing the `LShiftL` node).

```
for ( int i = 0; i < N; i++ )
    A[i] = i * i;
```

Listing 4: Example loop for the implementation

### 3.3 Detecting Target Loops

Section 2.2 formally described the shape of loops targeted by the proposed optimization. This section describes how our implementation detects them in the IG.

Section 2.2 defined the loops **Approximate Unrolling** can target. Fortunately, Java `for` loops having a constant-increment update expression are also the target of other well known optimizations such as Range Check Elimination and Loop Unrolling. Therefore, the C2 recognizes them and marks their start using `CountedLoop` nodes. When our optimization kicks in, the compiler has already marked the loops with `CountedLoop` nodes, recognized the nodes belonging to the update expression and the ones belonging to the loop’s body. The compiler does this using the works of Click[11],

Figure 5: The ideal graph of the example loop of listing 4. Dashed arrows represent control edges and solid arrows represents data edges.

Vick, [40] and Tarjan [37]. Figure 5 shows the `CountedLoop` recognized by the C2 for the loop in listing 4. The nodes in the graph are those listed in the `CountedLoop` metadata. This metadata also indicates that the update expression contains solely the `AddI` node (in gray).

Once the loops with constant-increment update expression are detected, the next step consists in determining if there is an array whose index expression value depends on the loop’s update expression. As we mentioned, the `CountedLoop` node maintains a list of all the nodes in its body. To determine if there is an array assignment within the loop, we look for a `Store` writing to memory occupied by an array. In the example of figure 5 we find the `StoreI` node (in gray).

Finally, we check if the array index expression value depends on the loop’s update expression. As the IG is a *Value Dependency Graph*, we look for a path of data edges between the `Store` node representing the array assignment and any node belonging to the loop’s update expression. In the example of figure 5 this path is highlighted using bold gray edges. Thanks to the metadata stored in `CountedLoop`, we know that the update expression only contains the `AddI` node. Therefore, in the example, the path is composed of the following nodes: `AddI`  $\rightarrow$  `Phi`  $\rightarrow$  `CastII`  $\rightarrow$  `ConvI2L`  $\rightarrow$  `LShiftL`  $\rightarrow$  `AddP`  $\rightarrow$  `AddP`  $\rightarrow$  `StoreI`.

### 3.4 Unrolling

Our implementation piggybacks in two optimizations already present in the C2 compiler: Loop Unrolling and Range Check Removal. At the point **Approximate Unrolling** kicks in, the compiler has already unrolled the loop and performed Range Check Removal.

Figure 6: The ideal graph for the unrolled loop of listing 4 before approximating. Solid arrows represent data edges.

Listing 6: Assembler code for the example loop using Approximate Unrolling

While unrolling, the compiler clones all the instructions of the loop's body. Figure 6 shows the IG once the loop of listing 4 has been unrolled. The cloning process introduces two `Store` nodes: `StoreI` and `StoreI-Cloned`. Due to C2's design, the cloned nodes belong to the even iteration of the loop. Once the loop is unrolled, **Approximate Unrolling** reshapes the graph to achieve the interpolated step by modifying one of the two resulting iterations. Nearest Neighbor modifies the even iteration, while Linear interpolation reshapes the odd iteration.

### 3.4.1 Nearest Neighbor Interpolation

As mentioned in section 3.2, a `Store` node takes two input data edges  $e_M$  and  $e_V$ . Edge  $e_M$  links with the node computing the memory address, while  $e_V$  links with node producing the value to write.

**Approximate Unrolling** performs nearest neighborhood interpolation by disconnecting the cloned `Store` node from the node producing the value being written (i.e. it deletes  $e_V$ ). In figure 6 this means to disconnect node `MulI-Cloned` (in gray) from node `StoreI-Cloned` by removing edge  $e_V$ .

This operation causes the node producing the value (in the example `MulI-Cloned`) to have one less value dependency and potentially become *dead* if it has no other dependencies. A node without value dependencies means that its computations are not being consumed and therefore is useless *dead code*. In this case, the node is removed from the graph. We recursively delete all nodes that do not have dependencies anymore, until no new dead nodes appear. In figure 6, we delete `MulI-Cloned` and then `AddI-Cloned`. This simplification of the IG translates into less instructions when the IG is transformed in assembler code.

After the removal, **Approximate Unrolling** connects the node producing the value for the original `Store` into the cloned `Store`. Figure 7 shows the shape of the IG after **Approximate Unrolling** has approximated the graph using nearest neighbor. Note that `MulI-Clone` and `AddI-Clone`

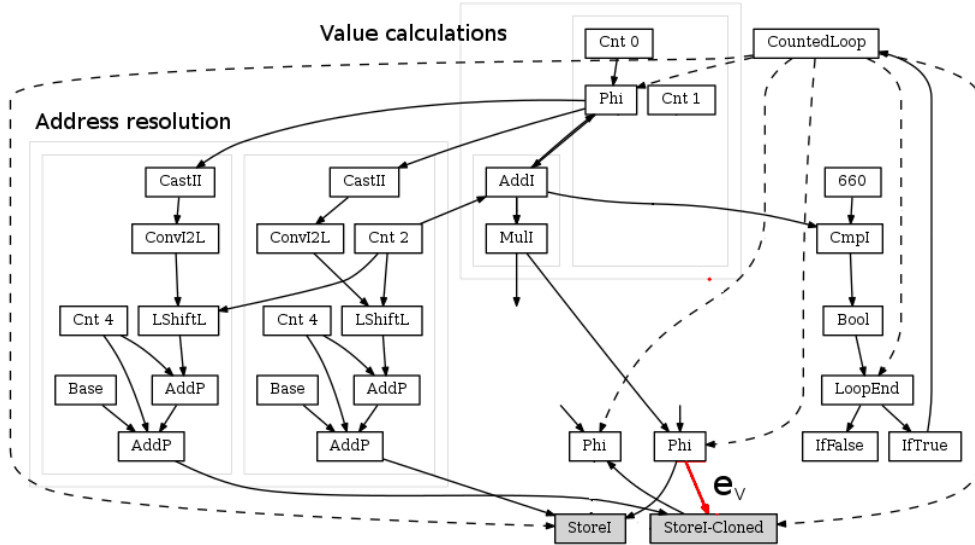

Figure 7: The ideal graph for the unrolled loop of listing 4 after Approximate Unrolling have modified the graph using nearest neighbor interpolation.

are deleted and that `Store-Clone` is connected by  $e_v$  to the same node as `StoreI`. The nodes producing the address remain different.

Listing 5 shows the code generated by C2, without performing **Approximate Unrolling**: the compiler has unrolled the loop twice, generating four storages to memory (lines 2, 3, 9, 10) and four multiplication instructions (`imull`, lines 5, 8, 12, 17). Listing 6 shows the code generated for the same loop using our transformation: there are still four storages (lines 4, 5, 9, 10), but only two multiplications (Lines 8, 13).

### 3.4.2 Linear Interpolation

To unroll using linear interpolation, **Approximate Unrolling** needs the first and last iteration of the loop peeled. Fortunately, this is also a requirement of other optimizations such as Range Check Removal and we exploit this feature to peel the first and last iterations of the loop. The current implementation of the Range Check Removal creates two guard loops, one before the main loop and other after. These guard loops ensure that the main loop will not go off bounds of the array being assigned. We exploit these two guard loops for the linear interpolation.

**Approximate Unrolling** performs linear interpolation following a process similar to nearest interpolation. The differences are that it disconnects the value data edge  $e_v$  from the original `Store`, rather than the cloned `Store`. This is because C2's design implies that the cloned nodes belong to the even iteration, but linear interpolation approximates odd iterations. After the value data edge is disconnected, some nodes become *dead*. Here we use the same process to remove unused nodes. Finally, the interpolation is performed in the following way: (i) a `Add` node is created that receives as input the output of the cloned `Store` and a `Phi` node representing merge between the previous odd iteration of the loop and the current one (ii) a `Mull` node is created to multiply the result of this addition by 0.5 and this node is

connected to the the original `Store` effectively interpolating the loop's even iteration.

## 4. EVALUATION

To evaluate our approach, we build a version of the software-based musical synthesizer `Osc3x`<sup>2</sup>. Using this synthesizer as case study, we run a series of experiments. The objective of our evaluation is twofold. First, we want to understand whether the accuracy loss caused by each optimized loop is significant or not. Second, we want to assess the benefits in performance and energy consumption of each optimized loop. We evaluate these concerns through the following research questions:

**RQ1: Is the accuracy loss caused by the optimization to each loop acceptable?**

If the accuracy loss goes to a point where the results are unacceptable there is no point in making the calculations faster. Therefore, we must carefully verify that our optimization reduces the accuracy only to acceptable levels. We introduce a metric in section 4.2, which is tailored to evaluate the accuracy of our case study.

**RQ2: How big is the execution times reduction per loop?**

On the other hand, without a significant increment in performance, reducing accuracy may not pay-off. Therefore, we must carefully assess these reductions to determine the actual gains in performance. In section 4.3, we implement we use microbenchmarks to estimate the computation time of each loop.

**RQ3: How big are the energy savings per loop?**

Just like with execution times, we expect to have energy savings in exchange of accuracy loss. We use JRALP to determine the energy consumption of each loop under study.

<sup>2</sup><https://www.image-line.com/support/FLHelp/html/plugins/3x%20OSC.htm>

Loop	Function	Executions in 20s (Min, Max)
A. Sine LFO	Generates a sine wave.	Between 441K - 1.2M depending on preset
B. Triangle LFO	Generates a triangular impulse	Between 441K - 1.2M depending on preset
C. Square LFO	Generates a square impulse	Between 441K - 1.2M depending on preset
D. Sawtooth LFO	Generates a sawtooth impulse	Between 441K - 1.2M depending on preset
E. Mixer	Mix the LFO's output in one signal	Mono: 441K - Stereo: 882 K
F. Low Pass	Filters out higher frequencies	Mono: 441K - Stereo: 882 K
G. High Pass	Filters out lower frequencies	Mono: 441K - Stereo: 882 K
H. Band Pass	Attenuates higher and lower frequencies around a range	Mono: 441K - Stereo: 882 K
I. Delay	Creates a delay effect	Mono: 441K - Stereo: 882 K
J. Phaser	Creates a phaser effect	Mono: 441K - Stereo: 882 K
K. Output	Copies the signal to the sound card's buffer	Mono: 441K - Stereo: 882 K

## 4.1 Evaluation Program & Dataset

Our version of Osc3x is based on **JSyn** [8], a software-based musical synthesizer framework. We choose **JSyn** to evaluate our approach because the framework works by connecting sound units that generate or manipulate signal using loops that are good candidates for **Approximate Unrolling**. The loops are usually a central piece of the **JSyn** units.

As shown in figure 8, Osc3x works by mixing together the signal produced by three low frequency oscillators (LFO). The mixer's output is then filtered using a digital biquad filter. We also added two sound effect (FX) units. The synthesizer can be configured by setting each oscillator type (Sine, Square, Triangle, Sawtooth), FX units effects (Delay, Phase), the filter type (LowPass, HiPass, BandPass) and the mixer's LFO level. This is called a preset. The oscillators, mixers, FXs and filters are built-in with **JSyn**, our implementation only connect them together.

For our experiments, we run Osc3x with 10 musical scores. The scores are well known tunes such as Star Wars and Super Mario Bros themes. Each score is played with 10 different presets, which are designed to test all the synthesizer features.

The case study music synthesizer contains 11 loops that **Approximate Unrolling** can target. In all cases each loop was the central piece of code for each **JSyn** unit conforming the synthesizer. Their function is described in table 1 and a letter from A to K to better represent them in figures 9, 10 and 11. The target loop are computational intensive, table 1 also shows the number of times each loop was executed to produce an arbitrary amount of 20 seconds of sound. Each loop execution counted for 10 iterations. The number of iteration is set by the **JSyn** engine to meet its real time requirements.

The code for our synthesizer, as well as all the microbenchmarks, resulting data and rendered sound files can be found on the webpage of the **Approximate Unrolling** project <sup>3</sup>.

## 4.2 RQ1: Accuracy Loss Assessment

To answer **RQ1** we render each score using all the presets without approximating any loop. This results in 100 sound files that we use as baseline. Then, we play the same scores with the synthesizer in which we approximate one loop at a time. This produces 11 sets of 100 sound files. We then perform a pairwise comparison to assess the accuracy loss created by approximating each loop. This experiment was

<sup>3</sup><https://github.com/approxunrollteam>

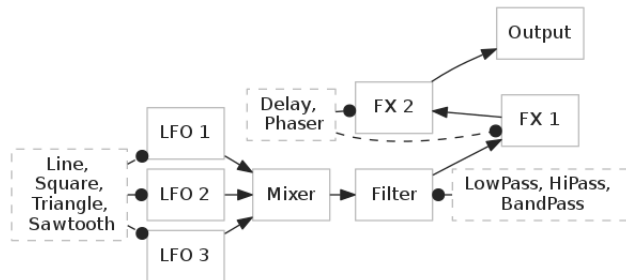

Figure 8: Diagram showing how the **JSyn** units are connected to build our **Osc3x** synthesizer.

repeated twice for each loop in the synthesizer: once using the nearest neighbor and once with linear interpolation.

Notice that it is possible that a given preset causes the execution of the synthesizer not to cover the approximate loop, in such case, the resulting file is not taken into account.

To compare two audio files we use the Perceptual Evaluation of Audio Quality (PEAQ) [42] metric. This is a standard metric designed to objectively measure the audio quality as perceived by the human ear. The metric was designed to compare sounds simulating the psychoacoustic of the human ear, which is not equally sensible to all frequencies. PEAQ takes one reference and one test file and compares them. It assigns a scale of contiguous value to the test audio, depending on how well it matches the reference: 0 (non audible degradation), -1 (audible but not annoying), -2 (audible slightly annoying), -3 (annoying) -4 (completely degraded).

## Results.

Figure 9 is a box plot showing the distribution of PEAQ measurements for each loop presented in Table 1 (we use the letters A to K to identify each loop). The gray boxes correspond to losses when using nearest neighbor transformation while white boxes correspond to losses when using linear interpolation. Boxes corresponding to linear interpolation can be also identified because the letter assigned to the loop is followed by an 'L'. This way, 'AL' means 'Sine LFO interpolated with linear interpolation'.

Globally, the accuracy loss is very much acceptable and stable for each loop. The accuracy reduction for loops A, B, C, D (Sine, Sawtooth, Square and Triangle LFOs) is always above the -1.5 line and in many cases over the -1 line,

Figure 9: PEAQ metric results for each approximate loop (0 to 1 - Not audible degradation; 1 to 2 - audible not annoying; 2 to 3 - slightly annoying; 3 to 4 - annoying; 4 & below - useless). Gray boxes represents loops approximated with nearest neighbor, while white boxes with linear interpolation.

Figure 10: Performance improvement for each approximate loop. Like before, gray boxes nearest neighbor approximation and while white boxes linear interpolation.

Figure 11: Energy consumption behavior for each approximate loop. Once again, gray boxes nearest neighbor approximation and while white boxes linear interpolation.

meaning that this reduction is not significant and in many cases undetectable by the human listener. We believe there are three reasons for this good performance (i) the produced signal’s nature is benign for interpolation as indeed these are locally smooth functions (ii) there were no accumulation in the error (i.e. the results mapped to  $y[i]$  are independent of those mapped to  $y[i + 1]$ ) (iii) the accuracy loss produced a harmonic distortion that was attenuated later by the synthesizer’s filters.

Loops F, G, H and I (representing the integrated LowPass, HighPass, BandPass filters and the Delay FX unit) appear as outliers in this experiment. The distortion was always audible and in some cases slightly annoying. We believe the main reason for this is the recursive nature of the functions governing both the filters and the delay. This accumulates error over time and eventually the resulting signal is more heavily distorted than in the case when non-recursive signals are approximate using **Approximate Unrolling**. For example, the recursive equation (2) governs the biquad filters units. Note that the resulting value  $y[n]$  depends on  $y[n - 1]$  and  $y[n - 2]$ , which we believe is the cause for the bigger losses in accuracy of loops F,G and H as the error accumulates.

$$y[n] = b_0x[v] + b_1x[n - 1] + b_2x[n - 2] - a_1y[n - 1] - a_2y[n - 2] \quad (2)$$

In general, loops interpolated with the linear interpolation degrade accuracy less than those approximated using nearest neighbor with exception of the loop implementing the Square LFO. This occurs because the governing equation for this unit ( $y[t] = \text{sgn}(\sin(t))$ ) had the property that in most cases  $y[t] = y[t+1]$ . Therefore, the nearest neighbor approximated loop version output is frequently the same that the original one.

Loops E, J and K, representing the LFO Mixer, the Phaser FX unit and the Output also yield good results ranging from non-audible to non-annoying. The computations in these loops did not accumulate error either.

### 4.3 RQ2: Execution Times Reduction

To evaluate the execution times of the optimized versions of the loops, we generate one microbenchmark per loop. We run the same microbenchmark with **Approximate Unrolling** turned on and off in the Virtual Machine and compared the execution times.

Determining whether there is an effective gain in terms of performance is a challenging task in Java [2]. We run our microbenchmarks using the statistical methodology introduced by George [15] to ensure that the measurements of each run were consistent. All runs were performed in an Intel i7 i7-6600U CPU, 2.60GHz with 16GB RAM running Linux Ubuntu 16.04.

#### Results.

Figure 10 shows the results obtained by running our microbenchmark set. In all cases, the performance boost using linear interpolation was slightly smaller. This is because of the mean calculation performed in this variant of **Approximate Unrolling**. However, compared to the computations skipped, the median computation is not so expensive and there not much difference in the performance of both optimizations.

All loops, except the D and K loops, run between 140%

and 180%. These is a remarkable benefit of our transformation: we can successfully increase the performance with little impact (or in some cases none) on the quality of the signal.

Loop D runs 200% faster than the original version. This is because its body is mainly composed of arithmetical operations only, which our implementation is very efficient removing.

It is interesting to notice that the optimized loop K (Output) actually runs slower. The accurate loop K simply copies the value of an array to another array. Therefore, the operations removed from the body are not more time consuming than the operations added by the nearest neighbor transformation and are even less time consuming than all computations added in the case of the linear interpolation.

### 4.4 RQ3: Energy savings

We evaluate our energy savings by estimating the total energy consumption of our microbenchmarks using JRALP [19], a Java library that exposes to Java programs the the Intel’s Running Average Power Limit (RAPL) Technology [1]. We first run the microbenchmark set and estimate energy consumption without optimizing any loop with **Approximate Unrolling**. In a second step, we repeated the experiment, this time turning the proposed optimization on and compared the energy consumption estimates of both runs.

#### Results.

The results displayed in figure 11 indicate a clear reduction in energy consumption for most loops. In general, most loops are able to reduce their consumption within 50% - 70 % range. Also, the transformation based on linear interpolation is less energy effective than nearest neighbor as it introduces a few more computations. Again, loop K was the counter example, as the optimization introduced more operations that the one it was able to remove.

## 5. DISCUSSION

Section 4 shows promising results as they indicate that **Approximate Unrolling** can actually reduce the execution times and energy consumption of optimized loops without a significant impact in the signal’s quality.

We choose to keep the data set small (11 loops), enabling us to provide a per-case analysis on the impact of the transformation on each loop and to understand the reasons behind the improvement (or not) in each case. The lessons learned on this case study drive the future work, as we now have a better understanding of which loops should gain more of the optimization. Loop K got its performance reduced because **Approximate Unrolling** interpolations were actually more expensive than the original loop. On the other hand, the LFO loops ran significantly faster and with less energy, without significant impact on the signal’s quality. We learned that this was due to the non-recursiveness and smoothness of the function being mapped to the array, as well as the capacity of the system being approximate (the Osc3x synthesizer) to absorb the accuracy loss.

As with other approximate computing techniques, **Approximate Unrolling** is effective in domains where some degree of inexactitude can be allowed, e.g. as video and sound, numerical simulations and games. We have evaluated **Approximate Unrolling** using a single domain of application. This certainly raises the question of the applicability of **Approximate Unrolling** outside the field of

sound. However, sound signals share many properties with other time series data such as sensor readings, stock share values and even video. Therefore, we believe **Approximate Unrolling** could be exploited in other domains as well.

Our results suggest that the situations in which **Approximate Unrolling** will work best are those in which the data stored close to each other in memory are also logically related to each other in the application’s data model. This is the case in numerous data representations, like sound, triangle strips, sensor data, market trends, etc. For example, in sensor data (such as sound recoding and weather) two consecutive array elements will represent two readings close to each other in time; in 3D visualizations, triangles topologically close to each other will be stored in contiguous array slots.

### *Threads to validity.*

We did extensive testing of our code and reviewed our microbenchmarks using best practices for microbenchmarking [15, 2]. However, Java microbenchmarking is a very difficult craft [2] and is possible to overlook a details skewing the measurement. Also, the Hotspot’s C2 is a very complex piece of code. We introduced a modification to this software and there may be bugs. We hope that if such is the case, they have only a marginal quantitative impact, and not distort the qualitative essence of our findings. Our infrastructure is publicly available on Github.

## 6. RELATED WORK

The quest for energy savings and performance has made Approximate Computing an attractive research direction in the last few years[25], [41], [29]. The approaches are numerous and diverse, as they use hardware, software or a mixture of both.

Hardware-oriented approximation techniques have proposed hardware components with approximation capabilities, such as FPUs that dynamically adapts the mantissa width [38], approximate adders [16, 33], memory designs that exploit voltage scaling [10, 18] or that allow bit flipping [20]. Also, general circuit design techniques has been proposed to exploit the accuracy-performance trade-off [5, 27, 39]. Another trend is to take advantage of an existing non-determinism of the hardware [21, 32, 35] or expose it to the developers to let them exploit it [7, 36].

On the other hand, software-oriented techniques proposes ways to approximate existing algorithms automatically [34, 24, 22, 28, 31] or provides support for programming using approximation [4, 6, 23, 30, 9].

Closest to our technique is Loop Perforation[34], which skip some iteration of the loop or terminate it early. Loop Perforation and **Approximate Unrolling** differs in the scope where they can best applied, as well in the transformation made to the code. Loop Perforation works better in patterns that can completely skip some task, like Monte-Carlo simulations, computations iteratively improving an already obtained result or explorations to filter or select elements in a given search space. **Approximate Unrolling** do not *skips* any iteration of the loop, instead, it *replaces* the computations of some iterations by approximate ones. **Approximate Unrolling** best results are obtained when applied in loops mapping values to arrays and works good even if no previous value was mapped before. By construction, it behaves better than Loop Perforation in situations

when no value of the array can be left undefined.

Another related technique to **Approximate Unrolling** is the Paraprox framework [28]. Paraprox works by detecting and proposing approximate alternative to patterns in parallel applications. One of the detected patters (stencil) also works on the assumption that nearby array elements are similar in image and video applications. Paraprox exploits this to skip memory accesses. **Approximate Unrolling** and Paraprox diverge in the sense that Paraprox uses the neighbor similarity to avoid memory accesses, while **Approximate Unrolling** uses it to avoid computations. The stencil pattern in Paraprox is also fine-tuned for Matrix arrays (images, videos), which is not the representation of sound or times series. This set apart both approaches w.r.t. the type of data each one is better suited for.

There are a number of approaches allowing the programmer to provide multiples alternatives to the same algorithm [6, 4]. In this context, **Approximate Unrolling** can be used as a way to provide one of such alternatives where accuracy can be exchanged for performance or energy savings. Similarly, several languages have been designed to indicate the parts of a program that can be approximate. Examples of this are EnerJ[30], FlexJava[26] and Rely[9]. Separating the parts of a program that can be approximate is an orthogonal concern to **Approximate Unrolling**. In our experiments we used EnerJ annotations to select one loop to approximate out of all the loops our optimization could target in the entire program, allowing us to assess the impact of a single loop each time and showing that our technique is indeed complementary with these approximate languages.

## 7. CONCLUSIONS & FUTURE WORK

In this paper we have described **Approximate Unrolling**, an a transformation that approximates the computation inside certain loops. We formally described the shape of the loops selected for **Approximate Unrolling**, as well as the transformations it performs to reduce execution times and energy consumption at the expenses of accuracy loss. We have also proposed an implementation of this transformation inside the OpenJDK Hotspot C2 Server compiler.

The empirical assessment of this transformation on the loops of the JSyn sound library demonstrated the ability of **Approximate Unrolling** to effectively trade accuracy for resource gains. We learned that not all loops respond equally well to the approximation and we gained some insights on the causes for this. Hence, our future work will consist in including these findings into the optimization, improving the detection process using a cost function that favors loops whose bodies (i) contains more instructions than the ones introduced by **Approximate Unrolling** (ii) have a minimal number of instructions depending on a value calculated in a previous iteration (iii) represents an smooth function. Then, the selection will filter out those loops below a given threshold of the cost function.

Another direction in the future is to assess the applicability of **Approximate Unrolling** in other domains. We focused this work on a single case study to gain precise insights about the nature of loops that can benefit from **Approximate Unrolling**. Yet, in future work we will evaluate the impact of approximating more loops and more iterations in each loop.
