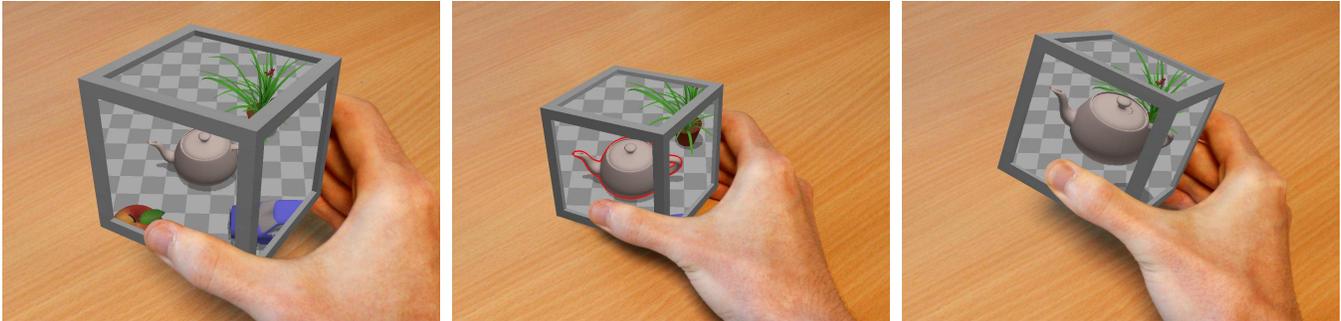

Figure 1: Our concept of a *tangible volume* consists of a fully portable and self-contained device, entirely covered with screens. A virtual scene can be seen “through” the volume of the device (left image). This volume can be directly positioned within the virtual scene (middle image), and used to grasp and manipulate virtual objects (right image). A cubic-shaped device is shown here for illustration, but other volume shapes can be used.

ABSTRACT

We present a new mixed reality approach to achieve tangible object manipulation with a single, fully portable, and self-contained device. Our solution is based on the concept of a “tangible volume.” We turn a tangible object into a handheld fish-tank display. Our approach, however, goes beyond traditional fish-tank VR in that it can be viewed from all sides, and that the tangible volume represents a volume of space that can be freely manipulated within a virtual scene. This volume can be positioned onto virtual objects to directly grasp them and to manipulate them in 3D space. We investigate this concept with a user study to evaluate the intuitiveness of using a tangible volume for grasping and manipulating virtual objects. The results show that a majority of participants spontaneously understood the idea of grasping a virtual object “through” the tangible volume.

Keywords: Tangible user interface, 3D manipulation, mixed reality, fish-tank VR

Index Terms: H.5.1 [Information Interfaces And Presentation]: Multimedia Information Systems—Artificial, augmented, and virtual realities

1 INTRODUCTION

Interaction with 3D data and, in particular, object manipulation [2] (selecting, translating and rotating 3D virtual objects) is of major importance in many fields, such as scientific visualization, prototyping, and gaming. Until recently, these tasks were often carried out by advanced users on fixed workstations. With the development of mobile computing, however, people are now expecting to perform these tasks anywhere, with minimal set-up and learning. There is thus a need for an interface that is not only *natural and efficient* for 3D manipulation, but also truly *portable and self-contained*.

Tangible User Interfaces (TUIs) represent a promising approach for 3D manipulation. They consist of physical objects, or tangible objects, that serve as real-world representations of digital data.

*e-mail: {paul.issartel,mehdi.ammi}@limsi.fr

†e-mail: {lonni.besancon,tobias.isenberg}@inria.fr

In many TUIs, tangible objects are used as physical “handles” for virtual objects. These interfaces take advantage of the user’s skills in interacting with physical objects [9], making them an attractive solution to support manipulation tasks in a natural and efficient way.

However, interacting with virtual objects also requires visual feedback. Tangible UIs for 3D manipulation often rely on an external and fixed monitor for visual output [6]. Hence, such interfaces cannot be considered portable. Others use mobile devices as a portable display surface [11]. Although these interfaces are portable, they still consist of multiple separate pieces, which always have to be handled and carried together—they are not self-contained. Some TUIs take a further step and use the mobile display as a physical handle [5]. The device itself replaces the external tangible objects, thereby reducing the entire interface to a single portable and self-contained object. This solution, however, does not eliminate the distance between the display and the virtual objects. Since the mobile display now serves as the tangible handle, this separation creates problems during manipulation, such as a shifted center of rotation or manipulated objects leaving the field of view.

In this paper, we examine a different approach. Rather than turning a mobile device into a tangible handle, we propose to turn a tangible object into a display. We present a first, partially simulated prototype in which the surface of a tangible object appears to be covered with multiple screens. We then use fish-tank rendering to display part of the virtual scene “through” the object. In contrast to object-oriented or geometric displays [12, 17], our tangible object becomes a tangible representation of a *volume* of virtual space. We introduce a “grasping” metaphor that consists in positioning this volume directly onto a virtual object, and pressing the fingers to pick up the object with the tangible volume. Thus, the separation between the tangible handle and the manipulated virtual object disappears. By solving the issues caused by this separation, our solution makes it possible to preserve the advantages of tangible manipulation in a fully portable and self-contained device.

2 BACKGROUND

2.1 Tangible user interfaces for 3D manipulation

The main idea behind Tangible User Interfaces (TUIs) is to give physical form to digital data [9, 10]. This is accomplished through the use of real-world objects—called *tangible objects*—that represent the

digital information. One particular type of TUI are Graspable User Interfaces [4], in which tangible objects serve as physical “handles” for virtual objects. Each handle can be attached to a virtual object. Users can then manipulate a virtual object by directly moving the corresponding tangible object. By taking advantage of the user’s preexisting skills in manipulating real-world objects [4, 9], this interaction mode provides a natural and immediately efficient approach to 3D manipulation.

A number of TUIs have been designed around this concept. For instance, Hinckley et al. [6] used passive tangible objects (“props”) tracked in mid-air to position and orient 3D medical data. The result was displayed on a separate computer screen. A limitation of these interfaces is, however, that they all require an external monitor or projector. This makes them essentially fixed installations. The lack of portability creates many constraints. Users need to go to a dedicated place in order to use the system. It cannot be carried between offices or brought home. Nowadays, with the rise of mobile computing such constraints appear even more limiting. There is a need for a truly portable interface that would offer the same advantages as fixed TUIs. Our first requirement is thus that the entire interface should be *portable*.

Since mobile devices—such as smartphones and tactile tablets—have become widespread, they represent a readily-available solution for use as a portable display surface. Some researchers have combined mobile device with tangible objects [11], resulting in portable TUIs. However, these interfaces also consist of multiple independent pieces: the mobile device and the tangible objects, all of which need to be carried together at all times. Whenever one of the tangible objects is missing, or when the mobile device is separated from the tangible objects, the interface becomes less functional or even unusable. The portability advantage is reduced due to the inconvenience of having to carry and keep the multiple pieces together. We can thus identify another requirement: the interface should not only be portable but should also consist of a single, *self-contained* device.

2.2 Mobile device as tangible handle

In addition to its role as a portable display surface, the mobile device itself can be seen as a tangible object. Several researchers have proposed to use the mobile device as tangible handle [5, 14] to manipulate virtual objects in the space behind the device (generally in augmented reality). This eliminates the need for external tangible props, resulting in an interface that is fully portable and self-contained in a single object: the mobile device.

Although this solution fully meets the portability requirements, it is not, however, without drawbacks. Unlike previous approaches, there is now a separation between the virtual objects (behind the device) and the tangible handle (the device itself). This separation leads to problems during manipulation. In the technique proposed by Henrysson et al. [5], the manipulated object is fixed relative to the device. Since the center of rotation is now located on the device, it becomes difficult to rotate a virtual object without also translating it (Figure 2(a)). In the HOMER-S technique [14], translations and rotations are separately applied to the manipulated object, which makes it easier to rotate the object about itself. On the other hand, the object is no longer fixed relative to the mobile device and can thus leave the field of view during rotations (Figure 2(b)). The authors suggest to alter the control-display ratio to avoid this limitation, but such an indirect mapping would become less natural than direct tangible manipulation.

One way to completely eliminate the separation and its associated problems would be to position the mobile device *onto* the virtual object before starting the manipulation. However, a typical rendering process would clip half of the virtual object in this situation—as well as everything else in front of the screen—making it difficult to manipulate the object properly (Figure 2(c)). In addition, most current mobile devices come in the form of flat one-sided displays.

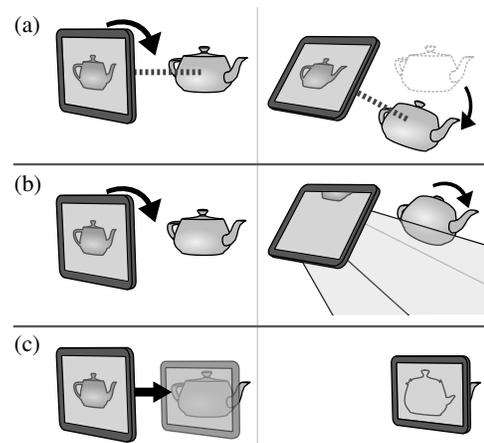

Figure 2: Manipulation issues that arise when a typical mobile device is used as a tangible handle: (a) the virtual object does not rotate about its own center; (b) the virtual object leaves the field of view; (c) when trying to reduce the distance to avoid the above issues, the virtual object is clipped.

Even if clipping was not an issue, this form factor would still result in loss of visual feedback during manipulation. Therefore, we can identify two additional requirements: the portable and self-contained device should provide visual feedback on its entire surface, and should be able to display virtual objects without clipping.

2.3 Fish-tank VR and geometric displays

When rendering a 3D scene, the display is generally considered as the viewpoint on the virtual world. This causes clipping whenever a virtual object crosses the screen plane. Fish-Tank Virtual Reality (FTVR) provides a solution to address the clipping problem. FTVR turns the display into a “window” seen from the viewpoint of the user [20]. This allows virtual objects to appear behind, onto, or in front of the display surface. There are two main ways to achieve this effect: stereo rendering, head-coupled perspective, or a combination of both [20]. According to Ware et al. [20], head coupling is a much stronger clue than stereo rendering, making it the preferred solution to implement this technique.

As explained before, a flat one-sided display is not the best shape for use as a tangible handle. A number of works have proposed volumetric objects equipped with multiple displays, capable of providing visual feedback on their entire surface. Some of these objects only support 2D rendering, such as the “Display Blocks” by Pla and Maes [16]. Others take advantage of FTVR to give the illusion of a 3D space inside the device. They are known as *geometric displays* [17], or object-oriented displays [12]. One of the first examples is the MEDIA cube [8]: multiple LCD displays were arranged in a box shape, and combined with head coupling to give the illusion that a virtual scene was inside the box. The CoCube [3] is a tangible cube that produced the same illusion when seen through a head-mounted display (HMD). Unlike the previous example, this tangible cube was freely manipulable by the user. The Cubee [18] is a cubic device that achieved the same goal without a HMD, by using integrated displays and a head tracker. The pCubee [17, 19] is an evolution of Cubee that was made smaller and more portable. Most of the above devices have a cuboid shape because this is the easiest way to arrange conventional rectangular displays, but other shapes are possible (ex. arbitrary polyhedra, sphere).

Geometric displays appear to meet all our requirements: they can be made small, portable, and self-contained, they provide visual feedback on all their surface, and with FTVR they can display virtual objects without clipping. However, previous work on this subject

was mainly focused on the feasibility of such displays. Although significant technological contributions have been made, the potential of such devices for 3D interaction remains comparatively unknown. In addition, there seems to be a lack of examples of positioning the geometric display itself within a larger virtual scene, which is an essential part of our concept. Even though the pCubee can be used to navigate in the virtual scene, this is accomplished through an indirect velocity-based mapping. In contrast, our concept is based on a full 1–1 mapping between the real world and the virtual world, which has greater potential for direct 3D interaction. In this work, we offer a new perspective on geometric displays, by considering such a device as a portable and self-contained TUI in its own right, capable of both displaying a virtual scene and serving as a tangible handle within the scene itself.

3 CONCEPT: A TANGIBLE VOLUME

Based on the above considerations, we introduce the concept of a “tangible volume.” A tangible volume is a single physical object, sufficiently small and lightweight to be held in the hand. The surface of this object is entirely covered in screens on which the virtual scene is displayed. The perspective of each screen is adjusted to the user’s head position. As a result, part of the virtual scene appears “through” the object. The object is also tracked relative to the real world. Users can reach other parts of the virtual scene by moving the object in real space (Figure 3). At any point, the physical boundaries of the object “enclose” a corresponding part of the virtual scene. Therefore, this object is a *tangible* representation of a *volume* of virtual space that can be held in the hand and directly positioned into the virtual scene.

We use this tangible volume as an interaction device for 3D object manipulation. First, the tangible volume is positioned *onto* a virtual object in the scene. From there, the virtual object is attached to the volume. The virtual object then follows the tangible volume in 3D space as if it was directly held in the hand (Figure 1). Thus, there is no separation between the virtual object and the tangible handle.

Our concept integrates all input and output into a single handheld object, used both to visualize the virtual scene and to manipulate virtual objects. Unlike the alternative approach of using a mobile device as a tangible handle, our interface also eliminates the separation from the manipulated virtual objects. Our concept thus constitutes a fully portable and self-contained interface for 3D object manipulation which avoids the problems described before.

3.1 Object selection by grasping

Having an interface made of an unique tangible object has clear benefits for portability, but also raises the question of how to interact with more than one virtual object. Such an interface must provide a way to attach and detach virtual objects from the single tangible handle.

In TUIs made of multiple tangible objects, each tangible object can be linked to a different virtual object. This allows the user to interact easily with multiple virtual objects, simply by manipulating the corresponding tangible objects as desired. This is called “space multiplexing” [4]. In our case, there is only one tangible object available to manipulate an arbitrary number of virtual objects. Therefore, the user has to *select* which virtual object should be linked to the tangible object at any given time. This is called “time multiplexing” [4]. While space multiplexing is considered more desirable than time multiplexing due to the lack of an object selection step which improves efficiency and lowers cognitive load [4], let us consider more closely what selection means in the specific case of tangible objects. Even though some interfaces allow the user to interact with multiple tangible objects concurrently, this is ultimately limited by the human capabilities. Tangible manipulation is typically performed with the hand(s). This means that all manipulation is accomplished through at most two effectors: the hands themselves. Any tangible object first has to be grasped with the hand in order to interact with the

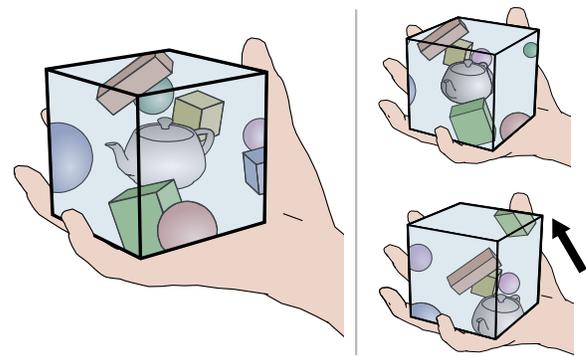

Figure 3: Illustration of our concept of a “tangible volume”. Part of a larger virtual scene can be seen through the tangible object held by the user. On the top right, the tangible volume is observed from a different angle. On the bottom right, the tangible volume has been translated in space and now encloses a different part of the virtual scene.

corresponding virtual object. Therefore, there is still an implicit selection in space-multiplexed TUIs that occurs when an object is grasped with the hand.

From that perspective, one of the main advantages of space multiplexed TUIs is not actually the lack of a selection step, but rather the fact this selection is implicit and does not require thinking. In other words, reaching for an object and grasping it with the hand constitutes a *natural* way to select it.

Grasping metaphor

The tangible volume provides a unique opportunity to reproduce this form of selection with virtual objects: by considering the volume as an extension of the hand. As shown above, the tangible volume can be moved in space and positioned around a virtual object. Since the volume is held in the hand, and is surrounding a virtual object, the hand is also surrounding the virtual object.

We thus designed a selection technique that consists in *pressing the fingers* on the tangible volume to “grasp” the virtual object located inside (Figure 4). Because the tangible volume is already held in the hand, the grasping technique is only triggered when finger pressure exceeds a given threshold. This threshold allows users to differentiate a conscious grasping action from normal manipulation of the tangible volume itself. Similarly, releasing the virtual object is done by releasing finger pressure below this threshold, while keeping hold of the tangible volume.

With our grasping metaphor, the action of picking up a virtual object becomes very similar to picking up a real-world object: placing the hand around an object, and pressing the fingers to grasp it.

3.2 Disambiguating between virtual objects

A challenge that arises from our grasping metaphor is that fingers cannot penetrate the volume. When virtual objects are close to each other, more than one may be located inside the volume bounds. Since fingers cannot be directly used to grasp the desired object, there must be a way to indicate which object will be selected among those located in the volume. One possible solution is to display an outline around the object that is closest to the center of the volume (Figure 4).

3.3 Bimanual manipulation

Space-multiplexed TUIs allow the user to manipulate different virtual objects in each hand. Since our interface is made of a single object, this form of bimanual manipulation is not directly supported. One solution could be to use two tangible volumes—one for each hand. Since our grasping metaphor makes the tangible volume an

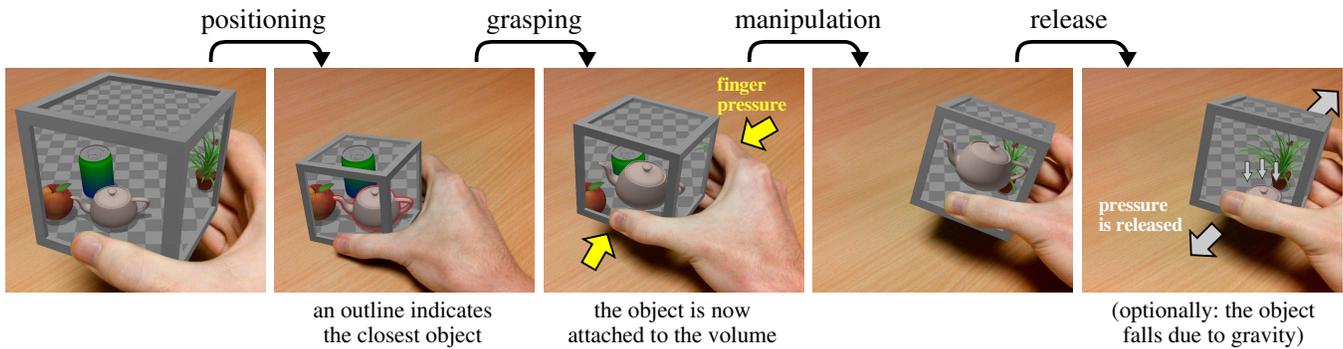

Figure 4: Illustration of the different steps of object manipulation in our interface concept. First, the tangible volume is positioned onto a virtual object. To disambiguate between nearby objects, an outline indicates which object is both inside the volume and closest to its center. This object can be grasped by pressing the fingers on the volume. The object is then attached to the volume, and can be directly moved alongside the volume in 3D space. The object is detached when finger pressure is released. If virtual gravity is enabled, it then falls to the ground.

extension of the hand, and all manipulation is accomplished through the hands, this solution would approximate space-multiplexed bimanual interaction. However, the interface would then again consist of multiple pieces, which we specifically wanted to avoid.

Still, as a single object, our interface supports another form of bimanual interaction: manipulating a single virtual object with both hands. This can be accomplished by holding the tangible volume with two hands, and pressing the respective fingers on opposite sides of the volume.

3.4 Simulated physics

In his dissertation on Graspable User Interfaces, Fitzmaurice [4], citing Norman [15], argues that the natural laws of physics that affect tangible objects help the user during manipulation. Indeed, in graspable UIs, releasing an object from the hand makes it drop to the floor due to gravity. This familiar behavior can help understand and predict its motion.

However, in our interface, the tangible volume always remains in the hand. Releasing a virtual object simply detaches the virtual object from the volume. Without further intervention, the virtual object would remain there—floating in space. We can obtain a more realistic behavior by adding simulated physics to the virtual scene. With physics, the released virtual object falls to the virtual ground when released (Figure 4). Simulated physics also prevents virtual objects from moving through each other. This reinforces the illusion that they are solid, and thus can be grasped and manipulated directly.

It should be noted that virtual physics is not always desirable. For example, a complex manipulation task may have to be decomposed in several steps in mid-air (clutching). With virtual gravity, releasing the virtual object between each step would cause it to drop from its intermediate positions. Virtual physics enhances realism, but is not necessarily appropriate for every application.

4 IMPLEMENTATION

In order to study the usability of our concept, we designed a preliminary prototype. As said before, our work primarily focuses on the interaction capabilities afforded by a tangible volume, rather than on the hardware side. Therefore, we used augmented reality (AR) to simulate some hardware aspects of our concept.

One may argue that existing geometric displays could have served as a basis to conduct user studies, without requiring AR simulation. However, existing implementations described in previous work were all lacking in key aspects of our concept. Some of these devices are fixed installations, not meant to be moved by the user [8]. Others are somewhat movable, but are still tethered to a larger workstation [13, 17]. The tangible volume as intended in our concept is

supposed to be fully portable and self-contained, and a tether wire could hinder manipulation [7]. Finally, some of these devices are only partially covered in screens [17, 18]. Even though this is sufficient to demonstrate the technology, for complex object manipulation (especially rotations) it is important that all sides of the volume provide visual feedback. Simulating an interaction device to conduct user studies has been done in previous work [1]. This approach has the advantage of providing flawless rendering and tracking, which would be difficult to achieve in a research prototype but essential for the validity of user studies.

We chose a cubic shape for the tangible volume in our prototype. Even though other shapes could have been used, we chose a cube because it was easier to build while also being easy to manipulate by users. This cube was covered with AR markers. We used a tactile tablet as an augmented reality window. When observed through the rear camera of the tablet, the faces of the cube were replaced with “virtual screens” that displayed part of the virtual scene with a fish-tank effect. A frame was added around each virtual screen, to account for the fact that real screens would not be completely borderless. Using AR provided implicit viewpoint tracking: since the cube faces were tracked by the camera, reversing this transformation produced an equivalent result. The cube was tracked relative to the real world by placing an additional AR marker in the environment. We employed the Vuforia framework¹ to track these objects. The tablet was attached to a raised stand, so that users could simply manipulate the object behind the tablet, as if they were directly looking at a cube equipped with screens.

Our grasping technique was implemented in actual hardware, by attaching six flat pressure sensors (Interlink® FSR 406) to the faces of the tangible cube. The sensors were located under the AR markers, and thus were invisible to the users. They were driven by a microcontroller² embedded in the cube (Figure 5). It was powered by a rechargeable battery, with a charging port hidden in one corner of the cube. The microcontroller continuously transmitted the pressure values to the rendering software on the tablet, through a wireless Bluetooth connection, at a frequency of 10Hz. Finally, we implemented physical simulation for the grasped objects with the Bullet³ physics engine.

In the rest of this paper, we use this prototype to investigate the intuitiveness of object manipulation with our grasping metaphor.

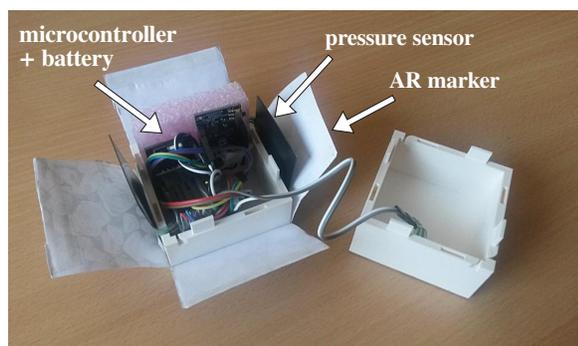

Figure 5: View of the electronic components inside the cube. The embedded microcontroller retrieves values from the pressure sensors on the cube surface, and sends them to the rendering software on the tablet through a wireless connection.

5 USER STUDY: OBJECT MANIPULATION

When interacting with the real world, grasping an object by pressing fingers on it, and moving it while maintaining finger pressure is a fairly natural procedure. However, it is unknown whether the exact same procedure remains natural when interacting with virtual objects through a tangible volume. We thus conducted an experiment to evaluate the *intuitiveness* of object selection and manipulation in our interface.

More specifically, we wanted to see if users can understand *by themselves* with no prior explanations, how to grasp and move virtual objects with our interface. Of course, if some users do not succeed without help, this measure alone would not be sufficient to understand why. Therefore, we also wanted to determine at which step of manipulation those users would need guidance on their initial encounter with the interface.

5.1 Participants and apparatus

This study was conducted with 36 unpaid participants (from 20 to 52 years old, mean=29.5, sd=9.4). None of them had any prior knowledge of our interface concept or our grasping metaphor. The apparatus was our AR-based prototype described in the previous sections. We slightly raised the pressure threshold to ensure that the grasping technique would only be triggered when truly intended by the participants.

5.2 Procedure

Before starting the experiment, we first told participants that it would consist in “manipulating the cube”. We then explained why there was also a tablet in front of them: to “simulate screens that should have been on the faces of the cube, but were not there due to technical limitations”. We followed by demonstrating how the cube turned into a cubic display when placed behind the tablet, and how a virtual scene could be seen through it. If our prototype had actual screens and head tracking, participants would likely have noticed all of this immediately. We did this short demonstration to ensure there was no confusion about our AR simulation. However, we gave them *no* explanation about how to interact with virtual objects.

We then introduced participants to the task: moving a virtual apple to a nearby target. The target was represented by a circle on the virtual floor (Figure 6), 6 cm to the right of the virtual object. Participants were told this task would have to be done “with the cube”. They were also specifically told to ignore the tablet for manipulation. Finally, we asked them to discover how to do that “by themselves, as far as possible”.

Obviously, we expected that some participants would not be able to complete the task without explanation. In order to understand how

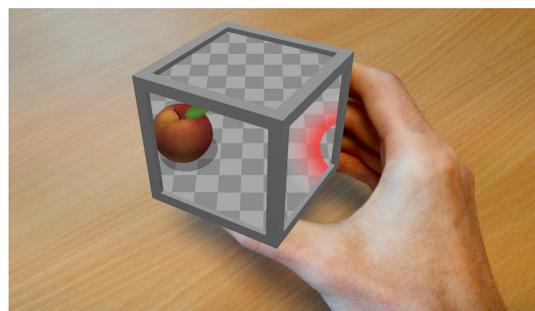

Figure 6: Screenshot of our first experiment, as seen by participants through the tablet. Note the lack of finger occlusion, due to the AR simulation. The task was to pick up the virtual apple and move it to the red circle on the right.

much help these participants needed, we designed a set of textual hints in increasing level of accuracy. During the task, there was a button that could be pressed to reveal a new hint. Each press on the button uncovered an additional hint on the tablet’s screen, in the following order:

1. “Put the cube onto the apple”
2. “Press the cube to grab the apple”
3. “Move the cube while maintaining the pressure”

These hints were specifically chosen to cover the different steps of object manipulation in our interface. Additionally, we chose to use textual hints rather than visual representations (e.g. arrows) to avoid ambiguous interpretations. We explained the role of the hint button to participants, and strongly encouraged them to use as few hints as possible.

5.3 Results and discussion

Figure 7 shows the percentage of participants according to the number of hints they needed to complete the task. A total of 19 participants (53%) successfully completed the task without requesting any hint. Among the remaining participants, all but one (45%) succeeded with the first two hints. The third hint was never used. We also reported the task completion times for the participants who accomplished the task without any hint. The mean completion time was 63.5 s (SD=34.3 s).

More than half of participants discovered by themselves how to grasp and manipulate virtual objects with our tangible volume. This is an encouraging result, given that our interface is so much different from the way most people currently interact with virtual 3D objects, and more generally interact with computers. At first glance, the completion times—about one minute on average—might seem long. However, this was the time needed to discover how to use a completely unfamiliar device *and* accomplish a manipulation task for the first time. This, it seems that the idea of grasping a virtual object “through” a tangible volume was spontaneously considered by a majority of participants, and within a reasonable time.

For those who did not complete the task without help, the number of hints requested provides more insight into which parts of manipulation were troublesome. The first hint was designed to uncover potential difficulties in positioning the tangible volume onto the virtual object. Nearly all participants who requested hints were not helped with this first hint. Hence, positioning was likely not what prevented them from completing the task. Indeed, all participants quickly noticed that an outline appeared around the virtual object whenever it was inside the volume. Some of them, however, believed that the outline meant the object was already selected, and attempted to move it without pressing the fingers.

Among other attempted strategies, a surprising number of participants attempted to “push” the virtual object with the tangible volume.

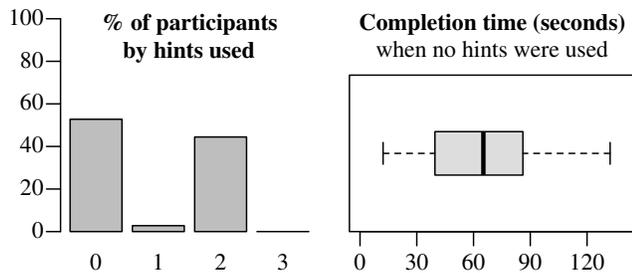

Figure 7: Number of hints and time needed by participants to discover how to manipulate a virtual object with our interface.

This may indicate they thought the sides of the volume would be solid in the virtual scene. Many tried to tap or flick their fingers onto the surface of the volume. In some cases, it was apparently an attempt to replicate the “click” metaphor, especially when they grasped the tangible volume as if it were a mouse and tried to click (and even double-click) on the top. In other cases, it was clearly an attempt to affect the virtual object through the volume, especially when flicking a finger against one of the side faces. Finally, some participants tried to fully enclose the cube in their hands. This may have been an attempt to grasp the virtual object. However, in doing so they lost visual feedback, and it was thus impossible to see if finger pressure was sufficient to trigger the grasping technique.

Nearly all participants who requested the first hint also requested the second hint to complete the task. The second hint was designed to uncover difficulties with the grasping metaphor itself. No participant ever asked for the third hint. For those who needed help, the grasping metaphor was therefore the main hurdle. The third hint was about moving the selected object by keeping it attached to the tangible volume. Since no participant requested this hint, none of them encountered any problem with this last step.

6 CONCLUSION

We introduced the concept of a “tangible volume”: a fully portable and self-contained device for 3D interaction, made of a single tangible object entirely covered with screens. In contrast to existing object-oriented or geometric displays, this tangible object represents a *volume of the virtual scene* and can be positioned directly onto virtual objects. This makes 3D interaction more direct than with previous approaches. We described an object manipulation technique that consists in grasping virtual objects “through” the volume and moving them in 3D space. We created a partial prototype based on this concept, and used this prototype to investigate some aspects of its usability. In particular, we showed that the grasping metaphor was spontaneously understood by a majority of users.

Future work should focus on two aspects. On the technical side, the first step would be to create a full implementation of our concept. This would require several improvements to the current technology. In particular, achieving reliable head tracking and environment tracking in a fully portable and self-contained device remains an important challenge, which has not been addressed so far by existing prototypes (Section 2.3). While recent devices with multiple included sensors such as the Tango tablet improve the situation, they still have issues with 3D tracking and we expect that future technological developments will provide better location data. On the experimental side, a more complete implementation would allow to repeat user studies in conditions that more closely resemble a real device. For example, the influence of correct finger occlusion could be studied in a prototype with actual screens, as well as the effect of possible imperfections in tracking and rendering.
