Abstract—This article studies distributed algorithms to control self-organizing swarm drone hotspots with massive MIMO networking capabilities - a network scenario referred to as *OrgSwarm*. We attempt to answer the following fundamental question: *what is the optimal way to provide spectrally-efficient wireless access to a multitude of ground nodes with mobile base stations/aerial relays mounted on a swarm of drones and endowed with a large number of antennas; when can we control the position of many-antenna-enabled drones, access association of ground nodes to drones, and the transmit power of ground nodes?*

The article first derives a mathematical formulation of the problem of spectral efficiency maximization through joint control of the movement of many-antenna-enabled aerial drones, access association of single-antenna ground nodes to many-antenna drones, and transmit power of ground nodes. It is shown that the resulting network control problem is a mixed integer nonlinear nonconvex programming problem (MINLP). We then first design a distributed solution algorithm with polynomial computational complexity. Then, a centralized but globally optimal solution algorithm is designed based on a combination of the branch and bound framework and convex relaxation techniques to provide a performance benchmark for the distributed algorithm. Results indicate that the distributed algorithm achieves a network spectral efficiency very close (over 95% on average) to the global optimum.

I. INTRODUCTION

The proliferation of innovative Internet of Things (IoT) applications, including intelligent transportation, wireless video surveillance, augmented reality, among others, has resulted in increasing demand for faster wireless communication links with higher spectral efficiency; as well as techniques to reduce interference between co-located links operating on the same spectrum bands and hence to increase the spectral efficiency [1]–[6]. This paper studies *OrgSwarm*, a new approach to provide ground connectivity by exploring infrastructure-less self-organizing swarm drone hotspots with massive MIMO networking.

With *OrgSwarm*, a swarm of many-antenna-enabled aerial drones collaboratively provide data collection/forwarding services to a group of single-antenna ground ad hoc nodes, and send to ground nodes control commands that are generated either locally at the drones or in a remote fusion center.

This work is based upon material supported in part by Air Force Research Laboratory under Contract FA8750-14-1-0074 and Grant ARMY W911NF-17-1-0034.

We attempt to provide an answer to the following question: *What is the best way to provide spectrally-efficient wireless access/networking to a group of ground nodes with mobile base stations/aerial relays mounted on drones and endowed with a large number of antennas; when you can control the movement of drones, access association, and transmit power of ground nodes?* We attempt to answer this compelling question by maximizing the spectral efficiency of *OrgSwarm* by jointly considering three tightly coupled network control strategies:

- *Movement control of drones.* Compared to infrastructure-based cellular networks with static massive MIMO base stations as in [7], [8], a peculiar feature of *OrgSwarm* is that many-antenna-enabled aerial drones need to move dynamically to adapt to changes in the location or traffic demands of ground nodes; nodes leaving or joining the network; as well as time and spatially-varying interference level, among others, to provide coverage with higher spectral efficiency.
- *Access association of ground nodes to drones.* This is jointly determined by several factors, including network topology (i.e., the relative locations of aerial drones and ground nodes), wireless channel quality currently experienced by ground nodes and transmit power of ground nodes, among others. Moreover, in a massive MIMO setting, a transmission is typically conducted in two phases: pilot-based channel estimation and data transmission. The maximum number of ground nodes associated to an aerial drone is constrained by the length (in symbols) of the pilot sequences used in the channel estimation phase [9], [10].
- *Massive-MIMO power control.* In *OrgSwarm*, all ground nodes are allowed to operate over the entire available spectrum band and at any transmission time. Therefore, it is imperative to regulate the transmit power of ground nodes to eliminate mutual interference in both channel estimation and data transmission phases caused by imperfect channel orthogonalization in the case of limited number antennas at each aerial drone, and hence to maximize the achievable SINR and spectral efficiency.

Clearly, the above three network control problems are tightly coupled and should therefore be jointly considered to obtain the optimal network operating point. Because of the binary ground-drone association variables (which will be clearer

in Section III), the resulting OrgSwarm control problem is a mixed integer nonlinear nonconvex programming problem (MINLP), which is generally NP-hard and there is no existing solution algorithm that can be used to obtain the globally optimal solution with polynomial computational complexity. This paper makes the following main contributions:

- *OrgSwarm control formulation.* We formulate mathematically the OrgSwarm control problem with control objective of maximizing the spectral efficiency of OrgSwarm by jointly controlling the movement of aerial drones, ground-drone association and transmit power of ground nodes.
- *Distributed solution algorithms.* Distributed solution algorithms are designed to solve the formulated OrgSwarm control problem based on primal decomposition, which decomposes the resulting MINLP problem into three distributed sub-problems: *single-antenna-to-many-antennas access association, massive MIMO power control, and drone movement.*
- *Globally optimal solution algorithm.* To provide a performance benchmark for the distributed solution algorithm, we design a centralized but globally optimal solution algorithm based on *a combination of the branch and bound framework and of convex relaxation techniques* that result in an ε -optimal solution of the original MINLP problem, where ε is a predefined level of optimality precision that can be set arbitrarily close to 1.
- *Performance evaluation.* The performance of the proposed distributed solution algorithm is evaluated in terms of network spectral efficiency by comparing it to the global optimum through extensive simulation experiments.

The remainder of the paper is organized as follows. We review related work in Section II, and describe the system model and problem formulation in Section III. In Sections IV and V, we present the distributed solution algorithm and the globally optimal solution algorithm, respectively. Performance evaluation is presented in Section VI, and finally we draw conclusions in Section VII.

II. RELATED WORK

There is a large and growing body of literature on unmanned aerial vehicular networking, focusing on UAV-assisted guidance [11], UAV-based data collection [12]–[14] and relaying [15]–[19], ground-aerial channel measurements [20] as well as tracking and control of UAV networks [21]–[23]. Readers are referred to [24]–[27] and references therein for an extensive survey of this research area. Most of these works focus on single-antenna aerial vehicles and conventional MIMO, with very few recent efforts considering massive MIMO [23]. Different from [23], where Chandhar et al. derived the achievable uplink capacity from a many-antennas ground base stations to a set of single-antenna aerial drones, in this paper we maximize the aggregate throughput of single-antenna ground nodes to a set of aerial drones each endowed with a large number of antennas.

Compared to conventional multiuser MIMO, massive MIMO can attain much higher spectral efficiency by using a large number of antennas with low-complexity linear precoding technologies [9], [28]–[33]. For example, in [29], the authors derived an exact achievable rate expression in closed-form for maximum-ratio combining/maximum-ratio transmission (MRC/MRT) processing and an analytical approximation of the achievable rate for zero-forcing (ZF) processing for multi-pair full-duplex massive MIMO relay system. In [30], Jin et al. derived ergodic rates for the case with a finite number of antennas and concluded that the ergodic sum-rate can be maintained while the relay power is scaled down by a factor of the number of the antennas at the relay over the number of users. Please refer to [7], [10], [34] for a good survey and tutorial on massive MIMO networking. These papers are focused on infrastructure-based cellular networks with static many-antenna-enabled base stations, and focus on asymptotic performance analysis with respect to a single network parameter (e.g., power). Our paper, instead, considers aerial drone hotspots with massive MIMO capabilities in an infrastructure-less network scenario.

III. SYSTEM MODEL AND PROBLEM STATEMENT

We consider infrastructure-less wireless ad hoc networks with many-antenna-enabled drones, where a set \mathcal{A} of many-antenna-enabled aerial drones are used to collect field information from a set \mathcal{G} of single-antenna ground nodes. The goal of the aerial drones is to collect field information, make action decisions either locally at each drone or by sending the information fusion results to a remote control center, and finally send the action commands back to ground nodes. We focus on information uploading over ground-drone links since it causes only low-level traffic load to transmit information fusion results and control commands back to ground nodes. Our objective is to *maximize the network-wide spectral efficiency by jointly controlling the movement of aerial drones, associating single-antenna ground nodes to many-antenna drones, and controlling the transmit power of ground nodes.*

Ground-Drone Association. We consider single-home accommodation for ground nodes in favor of tractable complexity in modeling and theoretical analysis, i.e., each ground node is associated with at most one drone. Denote the association vector as $\alpha \triangleq (\alpha_g)_{g \in \mathcal{G}}$, where $\alpha_g \triangleq (\alpha_{ga})_{a \in \mathcal{A}}$ is the association vector of ground node $g \in \mathcal{G}$, with $\alpha_{ga} = 1$ if ground node g is associated with drone a and $\alpha_{ga} = 0$ otherwise. Denote $\mathcal{A}_g \subset \mathcal{A}$ as the set of aerial drones ground node g is associated with, $\mathcal{G}_a \subset \mathcal{G}$ as the set of ground nodes associated with drone a , and A_g and G_a as the number of aerial drones in \mathcal{A}_g and the number of ground nodes in \mathcal{G}_a , respectively. Then, we have

$$\mathcal{A}_g \triangleq \{a | a \in \mathcal{A}, \alpha_{ga} = 1\}, \forall g \in \mathcal{G}, \quad (1)$$

$$A_g \triangleq |\mathcal{A}_g| \leq 1, \forall g \in \mathcal{G}, \quad (2)$$

$$\mathcal{G}_a \triangleq \{g | g \in \mathcal{G}, \alpha_{ga} = 1\}, \forall a \in \mathcal{A}, \quad (3)$$

$$G_a \triangleq |\mathcal{G}_a| \leq G_{\max}, \forall a \in \mathcal{A}, \quad (4)$$

where G_{\max} is the maximum number of ground nodes that can be served by each aerial drone $a \in \mathcal{A}$.¹

Ground-Drone Link Capacity. In massive MIMO networks, a transmission is typically accomplished in two phases, i.e., channel estimation and data transmission [9], [10], [36]. In the first phase, ground nodes send a set of orthogonal pilot sequences to their service aerial drones for channel estimation. Denote τ as the length (in symbols) of each pilot sequence. For ground node $g \in \mathcal{G}$, let \mathcal{I}_g represent the set of ground nodes using the same pilot sequences as node g , and $a(g)$ denote the service aerial drone of ground node g . Let $\mathbf{p} = (p_g)_{g \in \mathcal{G}}$ represent the transmit power vector of ground nodes, with p_g being the power of g th ground node in \mathcal{G} . Then, the achievable signal-to-interference-plus-noise ratio (SINR) of ground node $g \in \mathcal{G}$, denoted as γ_g , can be written as [37]

$$\gamma_g = \frac{(M - G_{a(g)}) \tau \rho \beta_{gg}^2 p_g / (1 + \tau \rho \xi_{gg})}{1 + \sum_{g' \in \mathcal{G}} \mu_{g'g} p_{g'} + \frac{\tau \rho (M - G_{a(g)}) \sum_{g' \in \mathcal{I}_g \setminus g} \beta_{g'g}^2 p_{g'}}{1 + \tau \rho \xi_{gg}}} \quad (5)$$

where M represents the number of antennas available at each aerial drone, $\beta_{g'g}$ is the slow fading channel gain between ground node $g' \in \mathcal{G}$ to the service aerial drone of ground node g , i.e., aerial drone $a(g)$, ρ is transmit signal-to-noise ratio (SNR), $\xi_{g'g} \triangleq \sum_{l \in \mathcal{I}_{g'}} \beta_{lg}$, and $\mu_{g'g}$ is defined as

$$\mu_{g'g} = \begin{cases} \beta_{g'g}, & \text{if } a(g') \notin \mathcal{A}(\mathcal{I}_g) \\ \beta_{g'g} \left(1 - \frac{\tau \rho \beta_{g'g}}{1 + \tau \rho \xi_{g'g}}\right), & \text{otherwise,} \end{cases} \quad (6)$$

with $\mathcal{A}(\mathcal{I}_g) \triangleq \{a(g') | g' \in \mathcal{I}_g\}$ representing the set of service aerial drones of interfering ground nodes in \mathcal{I}_g .

Let $\mathbf{x} = (x_a)_{a \in \mathcal{A}}$, $\mathbf{y} = (y_a)_{a \in \mathcal{A}}$, $\tilde{\mathbf{x}} = (\tilde{x}_g)_{g \in \mathcal{G}}$ and $\tilde{\mathbf{y}} = (\tilde{y}_g)_{g \in \mathcal{G}}$ respectively represent the coordinate vectors of aerial drones and ground nodes, with x_a, y_a being x- and y-axis coordinates of aerial drone a , and \tilde{x}_g and \tilde{y}_g being x- and y-axis coordinates of ground node g , respectively. Then, the slow fading channel gain $\beta_{g'g}$ in (6) can be expressed as

$$\beta_{g'g} = H_{g'g}(\mathbf{x}, \mathbf{y}, \tilde{\mathbf{x}}, \tilde{\mathbf{y}}) \zeta_{g'g}, \quad (7)$$

where $\zeta_{g'g}$ represents the log-normal slow fading between ground node g' and the service aerial drone of ground node g , i.e., aerial drone $a(g)$, $H_{g'g} \triangleq d_{g'g}^{-\chi}(\mathbf{x}, \mathbf{y})$ is location-dependent path loss with χ being path loss factor and $d_{g'g}^{-\chi}$ being the distance (in meter) between ground node g' and aerial drone $a(g)$. Then, the capacity achievable by ground node $g \in \mathcal{G}$, denoted as $R_g(\boldsymbol{\alpha}, \mathbf{p}, \mathbf{x}, \mathbf{y}, \tilde{\mathbf{x}}, \tilde{\mathbf{y}})$, can be expressed as

$$R_g(\boldsymbol{\alpha}, \mathbf{p}, \mathbf{x}, \mathbf{y}, \tilde{\mathbf{x}}, \tilde{\mathbf{y}}) = B \log_2(1 + \gamma_g), \quad (8)$$

where B is bandwidth (in Hz) and $\gamma_g = \gamma_g(\boldsymbol{\alpha}, \mathbf{p}, \mathbf{x}, \mathbf{y}, \tilde{\mathbf{x}}, \tilde{\mathbf{y}})$ is the achievable SINR defined in (5).

¹The maximum number of served ground nodes cannot exceed the number of antennas available to each aerial drone and the length of pilot sequences used in channel estimation [35].

Problem Statement. The network control objective can then be stated as maximizing the sum capacity of all ground nodes in \mathcal{G} and hence the network spectral efficiency by jointly determining transmit power vector \mathbf{p} for ground nodes, coordinate vectors \mathbf{x} and \mathbf{y} for aerial drones, and ground-drone association vector $\boldsymbol{\alpha}$. The problem is a mixed integer nonlinear nonconvex programming problem (MINLP) because of the nonlinear nonconcave mathematical expression of γ_g with respect to $\boldsymbol{\alpha}, \mathbf{p}, \mathbf{x}, \mathbf{y}$ in (5)-(7) and binary association variables $\boldsymbol{\alpha}$. Given an arbitrary such problem, how to design distributed solution algorithms to achieve the global optimum is still an open problem. In the following sections, we first present a distributed solution algorithm in Section IV and then design a centralized but globally optimal solution algorithm in Section V to provide a performance benchmark for the distributed solution algorithm.

IV. DISTRIBUTED SOLUTION ALGORITHM

A key step of the distributed solution algorithm design is to decompose the original network control problem into a series of subproblems, by solving which in a distributed manner the original problem can be solved. In our case, network control variables $\boldsymbol{\alpha}, \mathbf{p}, \mathbf{x}, \mathbf{y}$ are tightly coupled with each other in the SINR γ_g expression in (5) and, therefore, in the achievable capacity in (8). This results in the fact that the resulting network control problem is architecturally undecomposable.² Therefore, we design our distributed solution algorithm by decomposing the network control problem following a primal decomposition approach. The core idea is to divide the feasible set of the original problem into multiple parts by fixing a subset of variables at each time; and solve the resulting subproblems iteratively [39]. In our case, primal decomposition can be accomplished by fixing the aerial drone location variables \mathbf{x}, \mathbf{y} , association variables $\boldsymbol{\alpha}$, and transmit power vector \mathbf{p} , resulting in three subproblems: *ground-drone association*, *ground node power control* and *drone movement*. In the following, we design an iterative distributed solution algorithm, where at each iteration the three subproblems are solved sequentially.

Massive MIMO Association. Let $\mathbf{x}^{(\nu)}$ and $\mathbf{y}^{(\nu)}$ represent the coordinates of aerial drones and $\mathbf{p}^{(\nu)}$ be the transmit power of ground nodes in current iteration ν . Then in iteration $\nu + 1$ the objective of the ground-drone association subproblem is to maximize the aggregate capacity of all ground nodes in \mathcal{A} by determining the association vector $\boldsymbol{\alpha}^{(\nu+1)}$ subject to association constraint (2), which is a nonconvex combinatorial problem. Next, inspired by the behaviors of interacting agents in real-time auctions [40], [41], we present an effective *Distributed Auction-based Association Strategy (DAAS)* by viewing the drones as *sellers* while the ground nodes as *buyers*.

The core idea of DAAS is to let ground nodes iteratively compete for association by reporting their own association

²A problem is architecturally decomposable if its dual problem obtained by introducing Lagrange multipliers can be rewritten into a set of subproblems, each of which can be solved locally in a single protocol layer and network device [38].

preferences to nearby aerial drones, which then make association decisions based on the received preference information. Denote $\mathcal{N}_g^{(\nu+1)} \subset \mathcal{A}$ as the set of nearby aerial drones of ground node $g \in \mathcal{G}$ (i.e., aerial drones in the communication range of the ground node). Then, the association preference of ground node g with respect to aerial drone $a \in \mathcal{N}_g^{(\nu+1)}$, denoted as λ_{ga} , can be computed as

$$\lambda_{ga} = \frac{\log(1 + \gamma_{ga})}{\sum_{a' \in \mathcal{N}_g^{(\nu+1)}} \log(1 + \gamma_{ga'})}, \quad (9)$$

where $\gamma_{ga'}$ represents the interference-free single-input-single-output (SISO) SINR, i.e., the SINR achievable with single antenna and without interference from other ground nodes [35], achievable by ground node g if associated to aerial drone a' . This can be defined as $\gamma_{ga'} \triangleq \rho \beta_{gg} |_{a(g)=a'}$ with ρ being the transmit SNR and $\beta_{gg} |_{a(g)=a'}$ being the fading coefficient. Denote $\lambda_a = (\lambda_{ga})_{g \in \tilde{\mathcal{N}}_a}$ as the preference vector aerial drone a receives from its nearby ground nodes in $\tilde{\mathcal{N}}_a \triangleq \{g | g \in \mathcal{G}, a \in \mathcal{N}_g\}$. Then, aerial drone a sorts λ_a in descending order and sends association offers to a preferred set of maximum G_{\max} of ground nodes, as follows,

$$\lambda_a^{\text{dsc}} = \underbrace{(\lambda_{g_1 a}, \lambda_{g_2 a}, \dots, \lambda_{g_{G_{\max}} a}, \dots)}_{\text{Preferred Ground Nodes}}. \quad (10)$$

Then, the association offer corresponding to the highest SISO SINR is accepted by a ground node if it receives multiple offers. The above procedures are repeated until no ground node receives multiple association offers.

In (9), the rationale of computing association preference based on interference-free SISO SINR is as follows. In massive MIMO settings, particularly when the number of antennas M is large, the received SINR is dominated by path loss and large scale shadowing and tends to the interference-free SISO SINR as $M \rightarrow \infty$. Therefore, the capacity with interference-free SISO SINR can serve as a good indication of association preference and can be computed with low computational complexity.

Massive MIMO Power Control. Given the coordinates of aerial drones $\mathbf{x}^{(\nu)}, \mathbf{y}^{(\nu)}$ and association vectors $\alpha^{(\nu+1)}$, the ground node power control subproblem can be expressed as

$$\begin{aligned} \text{Given : } & \quad \mathbf{x}^{(\nu)}, \mathbf{y}^{(\nu)}, \alpha^{(\nu+1)} \\ \text{Maximize : } & \quad \sum_{g \in \mathcal{G}} R_g(\mathbf{p}) \\ \text{Subject to : } & \quad 0 \leq p_g \leq p_0, \forall g \in \mathcal{G} \end{aligned} \quad (11)$$

where $R_g(\mathbf{p})$ is defined in (5)-(8) and p_0 is the maximum transmit power of ground nodes. As stated in the following theorem, this problem can be approximated as a convex programming problem in the setting of massive MIMO networking, and hence the optimal power control can be achieved with poly-nominal computational complexity.

Proposition 1. *In a massive MIMO setting, for given coordinates of aerial drones and association strategies, ground node transmit power control problem in (11) can be approximated as a convex programming problem.*

Proof. According to convexity preserving properties, the logarithm of a concave function is a concave function [42]. Therefore, to prove the theorem we only need to show that the achievable capacity R_g in (8) is a concave function. In a massive MIMO setting, it is reasonable to assume that the achievable SINR γ_g in (5) satisfies $\gamma_g \gg 1$ since the negative effects of interference and small scale fading can be largely smoothed out [35]. Then, it can be shown that the expression of capacity R_g in (8) has the form of *minus-log-sum-exp* with respect to logarithm transformation of transmit power variables p_g , which is a concave function [42]. \square

Drone Movement. In this subproblem, each aerial drone determines its own best coordinates to adapt to the changes in association strategies and transmit power of ground nodes caused by solving the previous two subproblems. With newly obtained association vector $\alpha^{(\nu+1)}$ and transmit power vector $\mathbf{p}^{(\nu+1)}$, the subproblem of aerial drone movement can be written, for each aerial drone $a \in \mathcal{A}$, as

$$\begin{aligned} \text{Given : } & \quad \alpha^{(\nu+1)}, \mathbf{p}^{(\nu+1)} \\ \text{Maximize : } & \quad \sum_{g \in \mathcal{G}_a} R_g(\mathbf{x}, \mathbf{y}), \\ \text{Subject to : } & \quad x_{\min} \leq x_a \leq x_{\max}, \\ & \quad y_{\min} \leq y_a \leq y_{\max}, \end{aligned} \quad (12)$$

where $x_{\min}, y_{\min}, x_{\max}$ and y_{\max} represent the minimum and maximum x- and y- coordinates, respectively, and \mathcal{G}_a represents the set of ground nodes associated with aerial drone a with given association vector $\alpha^{(\nu+1)}$. In this subproblem, the mathematical expression of utility function $R_g(\mathbf{x}, \mathbf{y})$ in (12) has a log-convex form, which is in general a nonconcave function with respect to coordinate variables \mathbf{x} and \mathbf{y} . In this paper we solve subproblem (12) using an interior point method [42] to search for locally optimal coordinates for each aerial drone in favor of a low-complexity distributed solution. In Section V, we will design a centralized but globally optimal solution algorithm at the cost of extra computational complexity.

Computational Complexity Analysis. In the distributed solution algorithm, the above three subproblems are solved iteratively and sequentially at each iteration. In the ground-drone association subproblem, the association strategy is determined iteratively. In each iteration, the association variable α_{ga} can be determined for at least one ground node, and therefore the maximum number of associations is $|\mathcal{G}|$, and the overall computational complexity of the association is $\mathcal{O}(|\mathcal{G}|)$. Both the power control and the aerial drone movement subproblems can be solved in polynomial computational complexity, i.e., $\mathcal{O}(|\mathcal{G}||\mathcal{A}|)$. Therefore, the complexity of the overall distributed solution algorithm is $\mathcal{O}(|\mathcal{G}||\mathcal{A}| + 1)$ for each iteration. The convergence of the proposed distributed solution algorithm will be studied in Section VI based on simulations, where results indicate that the algorithm can converge very fast, i.e., within tens of iterations.

So far, we have presented a distributed solution algorithm to jointly control the movement of aerial drones, ground-drone association and power control of ground nodes

in infrastructure-less wireless ad hoc networks with many-antenna-enabled aerial drones. A natural question is: *How does the distributed solution algorithm compare to the global optimum in terms of aggregate spectral efficiency?* In the remaining of the paper we answer this question by designing a centralized but globally optimal solution algorithm to provide a performance benchmark for the distributed solution algorithm.

V. GLOBALLY OPTIMAL SOLUTION ALGORITHM

As stated in Section III, the “social” objective of the network control problem is to maximize the network spectral efficiency by jointly controlling movement of aerial drones, the transmit power of ground nodes and the ground-drone association strategies. The social OrgSwarm control problem can be mathematically represented as

$$\begin{aligned}
& \text{Given :} && \mathcal{A}, \mathcal{G}, G_{\max} \\
& \text{Maximize :} && U \triangleq \sum_{g \in \mathcal{G}} R_g(\boldsymbol{\alpha}, \mathbf{p}, \mathbf{x}, \mathbf{y}) \\
& \text{Subject to :} && 0 \leq p_g \leq p_0, \forall g \in \mathcal{G}, \\
& && x_{\min} \leq x_a \leq x_{\max}, \forall a \in \mathcal{A}, \\
& && y_{\min} \leq y_a \leq y_{\max}, \forall a \in \mathcal{A}, \\
& && (1), (2), (3), (4).
\end{aligned} \tag{13}$$

In (13), the individual throughput R_g is a nonconvex/nonconcave function with respect to coordinates variables \mathbf{x}, \mathbf{y} and transmit power vector \mathbf{p} . Moreover, the association variables $\boldsymbol{\alpha}$ take only binary values. Therefore the resulting network control problem is a mixed integer nonlinear nonconvex programming problem (MINLP), for which there is in general no existing solution algorithm that can be used to obtain the global optimum in polynomial computational complexity. In this paper, we design a globally optimal solution algorithm based on a combination of the branch and bound framework and of convex relaxation techniques [43], [44].

A. Overall Algorithm

Denote $\Gamma_0 = \{\boldsymbol{\alpha}, \mathbf{p}, \mathbf{x}, \mathbf{y} \mid \text{constraints in (13)}\}$ as the feasible set of initial problem (13) and let $U^*(\Gamma_0)$ represent the global optimum of problem (13) over Γ_0 , then the objective of our algorithm is to iteratively search for a U so that

$$U(\Gamma_0) \geq \varepsilon U^*(\Gamma_0), \tag{14}$$

where $\varepsilon \in (0, 1]$ is predefined optimality precision. To this end, the algorithm maintains a set $\Gamma = \{\Gamma_i, i = 0, 1, 2, \dots\}$ of subproblems by iteratively partitioning feasible set Γ_0 into a series of smaller subsets (see Section V-C).³ The algorithm also maintains a global upper bound $\bar{U}_{\text{glb}}(\Gamma_0)$ and a global lower bound $\underline{U}_{\text{glb}}(\Gamma_0)$ on $U^*(\Gamma_0)$ so that

$$\underline{U}_{\text{glb}}(\Gamma_0) \leq U^*(\Gamma_0) \leq \bar{U}_{\text{glb}}(\Gamma_0) \tag{15}$$

to drive the iterations of subproblem partitions, as follows.

- *Global upper bound $\bar{U}_{\text{glb}}(\Gamma_0)$:* For each subproblem $\Gamma_i \in \Gamma$, the algorithm computes a local upper bound

$\bar{U}_{\text{lcl}}(\Gamma_i)$ on network utility function U via *convex relaxation* (see Section V-B). Then the global upper bound $\bar{U}_{\text{glb}}(\Gamma_0)$ can be updated as

$$\bar{U}_{\text{glb}}(\Gamma_0) = \max_{\Gamma_i \in \Gamma} \{\bar{U}_{\text{lcl}}(\Gamma_i)\}. \tag{16}$$

- *Global lower bound $\underline{U}_{\text{glb}}(\Gamma_0)$:* Similarly, for each subproblem $\Gamma_i \in \Gamma$ a local lower bound $\underline{U}_{\text{lcl}}(\Gamma_i)$ is computed based on the solution obtained by solving the relaxed convex network control problem. Then the global lower bound $\underline{U}_{\text{glb}}(\Gamma_0)$ can be updated as

$$\underline{U}_{\text{glb}}(\Gamma_0) = \max_{\Gamma_i \in \Gamma} \{\underline{U}_{\text{lcl}}(\Gamma_i)\}. \tag{17}$$

The algorithm terminates if $\underline{U}_{\text{glb}}(\Gamma_0) \geq \varepsilon \bar{U}_{\text{glb}}(\Gamma_0)$ is reached and the global optimum $U^*(\Gamma_0)$ is set to $U^*(\Gamma_0) = \bar{U}_{\text{glb}}(\Gamma_0)$ as an upper-bound benchmark. Otherwise, the algorithm selects a subproblem from Γ and further partitions its feasible set into two smaller subsets, computes local upper and lower bounds and updates the global bounds $\bar{U}_{\text{glb}}(\Gamma_0)$ and $\underline{U}_{\text{glb}}(\Gamma_0)$ as in (16) and (17), respectively. In our algorithm, we select the subproblem $\Gamma_i \in \Gamma$ with the highest local upper bound to partition, i.e.,

$$\Gamma_i = \arg \max_{\Gamma_i} \bar{U}_{\text{lcl}}(\Gamma_i). \tag{18}$$

Based on the global bounds update criterion in (16) and (17), the gap between the two global bounds converges to 0 as the partition progresses. Furthermore, from (15), $\underline{U}_{\text{glb}}(\Gamma_0)$ and $\bar{U}_{\text{glb}}(\Gamma_0)$ converge to the global optimum $U^*(\Gamma_0)$.

B. Convex Relaxation

For each subproblem $\Gamma_i \subset \Gamma$, which is MINLP in our case, a key step is to obtain a relaxed but convex version of Γ_i so that it is easy to compute a tight local upper bound $\bar{U}_{\text{lcl}}(\Gamma_i)$. In this paper the convex relaxation is designed following a two-phase approach as follows.

Phase 1: In this phase the relaxation is accomplished by assuming i) there is no mutual interference among ground nodes, i.e., interference items in the denominator of (5) are set to zero, and that all ground nodes use different pilot sequences in channel estimation and hence $\xi_{gg} = 0$ in (5); ii) the maximum number of ground nodes that can be associated to an aerial drone is not limited to G_{\max} in (4). Then, the objective of the relaxed network control problem is to maximize the aggregate capacity of ground nodes by determining the optimal coordinate \mathbf{x} and \mathbf{y} of drones, i.e.,

$$\begin{aligned}
& \text{Maximize :} && U \triangleq \sum_{g \in \mathcal{G}} R_g(\mathbf{x}, \mathbf{y}) \\
& \text{Subject to :} && x_{\min} \leq x_a \leq x_{\max}, \forall a \in \mathcal{A}, \\
& && y_{\min} \leq y_a \leq y_{\max}, \forall a \in \mathcal{A},
\end{aligned} \tag{19}$$

where $R_g(\mathbf{x}, \mathbf{y}) = B \log_2(1 + \gamma_g(\mathbf{x}, \mathbf{y}))$ with $\gamma_g(\mathbf{x}, \mathbf{y})$ defined

³In this paper we use Γ_i to refer to both subproblem i and the corresponding feasible set.

in (5). Since $\gamma_g(\mathbf{x}, \mathbf{y}) \gg 1$, $R_g(\mathbf{x}, \mathbf{y})$ can be approximated as

$$R_g(\mathbf{x}, \mathbf{y}) \approx B \log_2(\gamma_g(\mathbf{x}, \mathbf{y})) \quad (20)$$

$$\leq B \log_2(M\tau\rho p_0 \zeta_{gg}^2 H_{gg}^2(\mathbf{x}, \mathbf{y})) \quad (21)$$

$$= B \log_2\left(\frac{M\tau\rho p_0 \zeta_{gg}^2}{d_{gg}^x(\mathbf{x}, \mathbf{y})}\right) \quad (22)$$

$$= B \log_2(M\tau\rho p_0 \zeta_{gg}^2) - \chi B \log_2(d_{gg}(\mathbf{x}, \mathbf{y})), \quad (23)$$

where the inequality in (21) holds since $G_{a(g)} \geq 0$ in (5), χ is path loss factor and $d_{gg}(\mathbf{x}, \mathbf{y})$ is distance (in meter) from ground node g to its service aerial drone $a(g)$.

Since $d_{gg}(\mathbf{x}, \mathbf{y})$ in (23) is a convex Euclidean norm with respect to \mathbf{x} and \mathbf{y} [42], $\log_2(d_{gg}(\mathbf{x}, \mathbf{y}))$ cannot be theoretically guaranteed to be concave. In this phase, we obtain a convex relaxation of (23) based on linear approximation of logarithmic function. To this end, we first replace $d_{gg}(\mathbf{x}, \mathbf{y})$ in (23) with t , then $\log_2(d_{gg}(\mathbf{x}, \mathbf{y}))$ in (23) can be represented as $\log_2(t)$ subject to $t \geq d_{gg}(\mathbf{x}, \mathbf{y})$. Then, $\log_2(t)$ can be further relaxed using a set of linear functions using a segment and three tangent lines.

Phase 2: Phase 2 of relaxation is invoked if the algorithm is done with partitioning coordinate variables \mathbf{x} and \mathbf{y} , i.e., for each aerial drone $a \in \mathcal{A}$,

$$x_{\max,a} - x_{\min,a} \leq \Delta x, \quad (24)$$

$$y_{\max,a} - y_{\min,a} \leq \Delta y, \quad (25)$$

where $x_{\max,a}$ and $x_{\min,a}$ ($y_{\max,a}$ and $y_{\min,a}$) are upper and lower bounds of x-axis coordinate x_a (y-axis coordinate y_a), and Δx and Δy are predefined movement step size of aerial drones in x- and y-axis, respectively. The objective in this phase is to determine the optimal association vector α with given aerial drones coordinates vectors \mathbf{x}^* and \mathbf{y}^* and without considering mutual interference among ground nodes as in Phase 1 relaxation. Let R_{ga} represent the capacity achievable by ground node $g \in \mathcal{G}$ if g is associated to aerial drone $a \in \mathcal{A}$, then the optimal association can be obtained by solving the

following linear optimization problem:

$$\begin{aligned} \text{Given : } & \mathbf{x}^*, \mathbf{y}^* \\ \text{Maximize : } & \sum_{a \in \mathcal{A}} \sum_{g \in \mathcal{G}} \alpha_{ga} R_{ga}(\alpha, \mathbf{x}^*, \mathbf{y}^*) \\ \text{Subject to : } & 0 \leq \alpha_{ga} \leq 1, \forall a \in \mathcal{A}, g \in \mathcal{G}, \\ & \sum_{g \in \mathcal{G}} \alpha_{ga} \leq G_{\max}, \forall a \in \mathcal{A}, \\ & \sum_{a \in \mathcal{A}} \alpha_{ga} \leq 1, \forall g \in \mathcal{G}. \end{aligned} \quad (26)$$

As variable partition progresses, the association variable α_{ga} becomes fixed either to 0 or 1 in all subproblems, for which the optimal transmit power \mathbf{p} can be obtained by solving a convex optimization problem as in Section IV.

C. Variable Partition

Variable partition can be conducted by partitioning association variable α and movement variables \mathbf{x} and \mathbf{y} . For example, given a subproblem $\Gamma_i \in \Gamma$, by fixing association variable α_{ga} subproblem Γ_i can be partitioned into two subproblems with feasible sets $\Gamma_{i,1} = \{(\alpha, \mathbf{p}, \mathbf{x}, \mathbf{y}) \in \Gamma_i | \alpha_{ga} = 0\}$ and $\Gamma_{i,2} = \{(\alpha, \mathbf{p}, \mathbf{x}, \mathbf{y}) \in \Gamma_i | \alpha_{ga} = 1\}$, respectively. For movement variables, say $x_a \in [x_{\min,a}, x_{\max,a}]$ for aerial drone $a \in \mathcal{A}$, the partition can be conducted by splitting x_a from the half, resulting in two subproblems with feasible sets

$$\Gamma_{i,1} = \{(\alpha, \mathbf{p}, \mathbf{x}, \mathbf{y}) \in \Gamma_i | x_a \in [x_{\min,a}, x_{\text{mid},a}]\}, \quad (27)$$

$$\Gamma_{i,2} = \{(\alpha, \mathbf{p}, \mathbf{x}, \mathbf{y}) \in \Gamma_i | x_a \in [x_{\text{mid},a}, x_{\max,a}]\}, \quad (28)$$

where $x_{\text{mid},a} \triangleq \frac{x_{\min,a} + x_{\max,a}}{2}$.

VI. PERFORMANCE EVALUATION

We evaluate the performance of the proposed solution algorithms by considering a network area of 1000×1000 m², with $N_g = \{4, \dots, 15\}$ ground nodes served by $N_a = \{2, 3\}$ aerial drones. The altitude of the drones are set to 100 meters. The number of antennas of each aerial drone is set to $N_{ant} = \{20, 40, \dots, 160\}$, the maximum transmit power of each ground node p_0 is set to $\{100, 200, \dots, 600\}$ mW, path loss factor is set to $\chi = 2$, and the average noise power

Fig. 1: Aggregate network spectral efficiency achievable by distributed solution algorithm and global optimum.

Fig. 2: Network spectral efficiency in the case of different number of ground nodes.

Fig. 3: Network spectral efficiency in the case of different number of aerial drone antennas.

is set to 10^{-8} mW. Results are obtained by averaging over 20 independent simulation instances with network topology randomly generated.

Performance of the proposed distributed solution algorithm is evaluated by comparing it with the global optimum obtained by the centralized solution algorithm designed in Section V. Figure 1 reports the network spectral efficiency achievable by the distributed solution algorithm and the centralized global optimum. It can be seen that the distributed solution algorithm achieves a performance very close to the global optimum in all the tested 20 instances, where 12 ground nodes and 2 aerial drones each with $M = 100$ antennas are considered. The average performance of the achievable network spectral efficiency is reported in Fig. 2 with different number of ground nodes. Results indicate that around 95% percent of the global optimum can be achieved by distributed solution algorithm, e.g., 94.9% and 95.4% with 6 and 10 ground nodes, respectively.

The network spectral efficiency is reported in Fig. 3 with the number of antennas at each aerial drone varying from 20 to 160 at step of 20. It can be seen that over 95% of the global optimum can be achieved by the distributed solution algorithm. Results also indicate that the achievable network spectral efficiency monotonically increases with the number of antennas but at a decreasing speed. With more than 100 antennas, the effect of increasing the number antennas is marginal.

In Fig. 4 we plotted the achievable network spectral efficiency against the maximum transmit power of ground nodes. Over 95% of the global optimum can be achieved by the distributed solution algorithms. We noticed that the network spectral efficiency rises only around 10% by increasing the maximum transmit power by 6 times from 100 to 600 mW. This is because in massive MIMO setting the network basically operates at high SINR regime, i.e., in bandwidth-limited regime. We further studied the effects of different network control strategies on the achievable network spectral efficiency in Fig. 5, where the joint network control strategy is compared

Fig. 4: Aggregate network spectral efficiency against the maximum transmit power of ground nodes.

Fig. 5: Achievable network spectral efficiency with different network control strategies.

to the other three strategies, in which aerial drone movement is randomly generated in “w/o Aerial Drone movement”, power control and association are executed only once in “w/o” power control and “w/o” association, respectively. It can be seen that the joint network control achieves the highest spectral efficiency in almost all tested instances. Results also indicate that a spectral efficiency close to that of joint control can be achieved by “w/o power control” in most network instances since the network operates in high SINR regime in massive MIMO setting.

VII. CONCLUSIONS

We studied infrastructure-less wireless ad hoc networking with many-antenna-enabled aerial drone hotspots. The network control objective is to maximize network-wide spectral efficiency by jointly controlling movement of drones, associating single-antenna ground nodes to many-antenna drones, and adapting transmit power of ground nodes. The network control problem was formulated as an integer nonlinear nonconvex programming problem (MINLP). Both distributed and globally optimal solution algorithms have been designed and evaluated with extensive simulation results. Results indicated that the distributed solution algorithm can achieve around 95% of the global optimum.
