ABSTRACT

Background: Standard of care for patients with high-grade soft-tissue sarcoma (STS) are being redefined since neoadjuvant chemotherapy (NAC) has demonstrated a positive effect on patients' outcome. Yet, response evaluation in clinical trials still remains on RECIST criteria.

Purpose: To investigate the added value of a Delta-radiomics approach for early response prediction in patients with STS undergoing NAC

Study type: Retrospective

Population: 65 adult patients with newly-diagnosed, locally-advanced, histologically proven high-grade STS of trunk and extremities. All were treated by anthracycline-based NAC followed by surgery and had available MRI at baseline and after 2 cycles.

Field strength/Sequence: Pre- and post-contrast enhanced T1-weighted imaging (T1-WI), turbo spin echo T2-WI at 1.5T.

Assessment: A threshold of <10% viable cells on surgical specimen defined good response (Good-HR). Two senior radiologists performed a semantic analysis of the MRI. After 3D manual segmentation of tumors at baseline and early evaluation, and standardization of voxel-sizes and intensities, absolute changes in 33 texture and shape features were calculated.

Statistical tests: Classification models based on logistic regression, support vector machine, k-nearest neighbors and random forests were elaborated using cross-validation (training and validation) on 50 patients ('training cohort') and was validated on 15 other patients ('test cohort').

Results: 16 patients were good-HR. Neither RECIST status, nor semantic radiological variables were associated with response except an edema decrease ($p=0.003$) although 14 shape and texture features were (range of p -values: 0.002-0.037). On the training cohort, the highest diagnostic performances were obtained with random forests built on 3 features: Δ _Histogram_Entropy, Δ _Elongation, Δ _Surrounding_Edema, which provided: AUROC=0.86, accuracy=88.1%, sensitivity=94.1%, specificity=66.3%. On the test cohort, this model provided an accuracy of 74.6% but 3/5 good-HR were systematically ill-classified.

Data conclusions: A T2-based Delta-Radiomics approach can improve early response prediction in STS patients with a limited number of features.

Level of evidence: 3

Technical Efficacy: 2

INTRODUCTION

Standard of care for locally advanced high-grade soft-tissue sarcomas (STS) has been recently redefined as phase 3 clinical trials demonstrated improved overall and metastasis-free survivals in patients treated with anthracycline-based NAC¹⁻³. Despite encouraging results of ¹⁸Fluorodeoxyglucose position emission tomography (¹⁸F-FDG-PET-CT), modified Choi criteria and dynamic-contrast enhanced MRI (DCE-MRI), evaluation of response to NAC still relies on RECIST 1.1⁴.

Non-invasive quantification of tumor heterogeneity and its changing phenotype during treatment is a recent, promising and challenging field of research referred to as radiomics. Radiomics techniques aim at leveraging big-data analytics and personalized medicine approaches in oncologic imaging^{5,6}. To achieve this, several numeric features are extracted to quantify and to screen tumor phenotype and surrounding tissue on any available imaging modality⁷. After a careful selection of features, machine learning algorithms can be designed and trained to answer crucial oncologic questions such as associations between imaging phenotypes and molecular subtypes with specific treatment and outcomes, prediction of response and patient outcome by including other –omics (genomic, transcriptomics) information within the model⁸.

Because of their complex morphology, architecture and changes during treatments, STS may be particularly appropriate to the radiomics approach. Indeed, radiomics on DWI may help to improve STS grading on microbiopsy⁹. In addition, Hayano et al. have demonstrated that texture parameters on CT-scan were associated with neoangiogenesis and overall survival for STS treated with radiotherapy and bevacizumab^{10,11}. STS heterogeneity assessed on ¹⁸F-FDG-PET-CT may be more predictive of survival as compared to classical measure of maximal standardized uptake value (SUVmax)¹². Recently, composite texture features from MRI and from ¹⁸F-FDG-PET-CT have enabled to identify aggressive tumors at risk of lung metastasis at baseline¹³. Together, these promising studies highlight the potential of radiomics applied to STS. However, to our knowledge, applications to response prediction to NAC have never been attempted.

Visual MRI evaluation of STS during NAC can highlight a wide range of morphologic alterations combining fibrotic and necrotic processes, infarction, bleeding, re-differentiation

or selection of resistant component. As change in longest diameter (LD) is not a sufficient criterion to predict therapeutic response, we hypothesized that a radiomics process could help predict NAC efficacy through the histologic response.

MATERIALS AND METHODS

Patients

The institutional review board approved this study and informed consent was waived.

All consecutive adult patients between June 2007 and June 2017 were included, as they presented with histologically proven high-grade STS of extremities or trunk wall, without metastasis on chest CT-scan, eligible for an anthracycline-based NAC according to the regional sarcoma reference center board. High-grade was defined as grade III STS according to the French Federation of Cancer Centers Sarcoma Group grading system¹⁴.

Criteria for inclusion were: measurable tumor with MRI, available MRI performed <28 days before the first cycle of NAC (: baseline, MRI_0) and between cycle 2 and 3 of NAC (: early evaluation, MRI_1), 4 to 6 cycles of NAC, histological response assessment on surgical specimen by an expert pathologist following published guidelines¹⁵. A threshold of <10% of viable cells assessed on whole tumor defined good histological response (good-HR)¹⁶.

Of the 163 patients with a newly diagnosed STS of trunk wall and extremities who underwent NAC at our institution (according to the pharmacology department), 28 patients were excluded because of non-anthracycline-based NAC, 20 because of less than 4 cycles of NAC, 33 because T2-weighted-imaging (T2-WI) was not performed at baseline, 7 because T2-WI was not performed at early evaluation, 10 because of non-diagnostic MRI at baseline and/or early evaluation.

MR imaging

Images were acquired in daily practice using 1.5-Tesla MR-systems from different radiological centers. Ninety-three examinations (72%) were carried out on a Magnetom AERA, (Siemens Healthineers, Erlangen, Germany). Coils, field-of-view and matrices were adapted to tumor location and size. To be considered as ‘diagnostic’, MRI must include at least 2D T2-WI turbo-spin echo (TSE) sequence without fat-suppression, T1-WI before and after Gadolinium-chelates injection (contrast-enhanced T1-WI, CE-T1-WI) and 2 orthogonal acquisition plans. Section thickness ranged from 3 to 5 mm. Ranges of repetition time / echo time were: 500-700/10-15 msec for T1-WI and 2400-6860/100-130 msec for T2-WI.

Semantic radiological features

Two senior radiologists (AC and MK, with 3 and 27 years of experience in STS imaging, respectively), independently reviewed the MRI blinded to patient data in a randomized fashion on a dedicated PACS workstation. They reported:

- LD in mm on MRI_0 and MRI_1, relative change in LD and RECIST response status.
- Percentage of tumor volume with changes compatible with fibrosis (low signal intensity (SI) on T2-WI, T1-WI, subtle enhancement) and/or necrosis (fluid-like SI on T2-WI, variable SI on T1-WI, no enhancement), as follows: 0%, <50% and $\geq 50\%$,
- Change in margin definition on CE-T1-WI ($\Delta_Margin_Definition$), as follows: ‘well-defined or better definition’ versus ‘stable ill-defined margins or worst’,
- Change in surrounding edema on T2-WI without or with fat-suppression technique when available (Δ_Edema), as follows: ‘none or decreased’ versus ‘stable or increased’,
- Changes in peritumoral enhancement on CE-T1-WI ($\Delta_Peritumoral_enhancement$), as follows: ‘none or decreased’ versus ‘stable or increased’.

One radiologist (AC) did a second reading 1.5 months later to assess intra-observer agreement (Supplemental Data). A consensual lecture was performed 3 months after for the statistical analysis.

MRI post-processing (Fi. 1)

Slice-by-slice 3D-delineation of whole tumor was manually made on T2-WI by one radiologist (AC) using the ROI manager of OSIRIX software. All slices were resampled using bi-linear interpolation to obtain a common isotropic in plane $1 \times 1 \text{ mm}^2$ pixel aspect. Signal intensities on T2-WI were normalized for non-uniform intensity (bias field correction¹⁷) and the intensity ranges were standardized using histogram-matching¹⁸ with the acquisition of a healthy volunteer’s thigh as reference. Thirty-three first- and second-order texture and shape features were computed using in-house Python software based on the ITK library¹⁹. The collected features and methods are detailed in Supplemental Data. We calculated the absolute change of a given feature ‘X’ for each patient as follows: $\Delta_X = X_{MRI_1} - X_{MRI_0}$.

Statistical analyses

Comparisons between good-HR and poor-HR were assessed with Student or Mann-Whitney tests depending on results to the Shapiro-Wilk normality test. Association of categorical and ordinal variables with response was assessed with Chi-2 and Fischer tests. Correlations

between features were assessed with Spearman's rank test. All tests were two-tailed. A p-value ≤ 0.05 was deemed significant.

To elaborate and validate the prediction model, the whole data set was partitioned in two: a training cohort (50 patients, included from June 2007 to June 2016) and a test cohort (15 patients, from July 2016 to June 2017 whose MRI were acquired after the initiation of the project). We initially selected only one feature per category (semantic, shape and texture categories) according to its lowest p-value at univariate analysis and lowest correlation with other significant features.

The selected combination of features was used to define models with 10-fold stratified cross validation on the training cohort. First, for each run and each set, the missing values were imputed with training features median and quantitative features were normalized by removing the training mean and scaling to unit variance. Several classification algorithms were evaluated using the scikit-learn library²⁰: random forests (RF), k-nearest neighbors (KNN), support vector machine (SVM) and logistic regression (LR). The parameters of those estimators were optimized by cross-validated grid-search (Supplemental Data). The selected classifiers were then trained with the whole 50-patients set and applied on the 15 patients from the test set using the same preprocessing method (Figure 1c).

The cross-validation step was repeated 100 times with shuffled folds composition. The full process (including the final test) was also repeated with different random initialization seed for the RF algorithm. Average test metrics are reported for each step: accuracy, area under the ROC curve (AUROC), specificity, sensitivity, positive predictive value (PPV), negative predictive value (NPV) and train score.

Finally, we increased the number of features that were included in the model in a forward stepwise fashion according to their p-value at univariate analysis and we calculated the corresponding classifiers test metrics.

RESULTS

Patient characteristics (Table 1)

The cohort included 65 patients (27 females, mean age: 57.9 ± 12.8 years old), of which 16 (24.6%) were good-HR. The most frequent histotypes were undifferentiated sarcoma (50.8%), followed by myogenic sarcoma (leiomyosarcoma and rhabdomyosarcoma, 20%). Most of them were deep-seated (93.8%) in the lower limb (58.5%). Twenty-two patients (33.8%) received 4 cycles of NAC in total.

Standard radiological assessment (Table 2)

No association was found between baseline epidemiologic characteristics and histological response. LD at baseline was significantly higher in good-HR (146 ± 66 mm vs. 110 ± 51 mm, $p=0.038$). Relative change in LD at early evaluation was also significantly different between good-HR and poor-HR ($-11.2 \pm 20.8\%$ versus $2.9 \pm 19.5\%$, $p=0.027$), however, response status according to RECIST 1.1 was not associated with histological response ($p=0.112$) as most good-HR and poor-HR were classified as stable disease by these criteria (81.3% and 79.6%, respectively). Of all the semantic radiological features, only Δ_Edema was associated with response ($p=0.003$), with substantial inter- and intra-rater agreements (0.637 and 0.769, respectively).

Radiomics assessment

The population study was partitioned in a training cohort (50 patients, 11 Good-HR) and a test set (15 patients, 5 Good-HR). There was no statistical difference between the training and test cohorts regarding the baseline epidemiological characteristics (Supplemental Data).

Within the training cohort, changes in twelve first and second order textural indices were associated with response at univariate analysis: $\Delta_Histogram_Entropy$ ($p=0.002$), Δ_Stdev ($p=0.008$), $\Delta_ClusterProminence_5$ ($p=0.038$), Δ_Energy_1 ($p=0.015$), Δ_Energy_2 ($p=0.014$), Δ_Energy_5 ($p=0.010$), $\Delta_Entropy_1$ ($p=0.005$), $\Delta_Entropy_2$ ($p=0.004$), $\Delta_Entropy_5$ ($p=0.003$), $\Delta_Homogeneity_1$ ($p=0.037$), $\Delta_Homogeneity_2$ ($p=0.022$), $\Delta_Homogeneity_5$ ($p=0.014$), as well as two shape features: $\Delta_Elongation$ ($p=0.019$) and $\Delta_Flatness$ ($p=0.019$) (Table 3). Correlation matrix demonstrated significant and strong correlations between all first and second order texture features (Table 4). Since the lowest p-value was obtained with $\Delta_Histogram_Entropy$ for texture features and $\Delta_Elongation$ for shape features, the initial selection for building the model included these two features and Δ_Edema .

Table 5 provides the performance of the classifiers for their optimal set of parameters and for this selection. On the training set, the highest mean accuracy was obtained with RF (88.1%), followed by LR (85.8%), KNN (80.5%) and SVM (75.2%). In an objective response setting, RECIST 1.1 provided one of the lowest accuracy with 76.0% of correctly predicted patients. In descending order, AUROC were 0.87 with LR, 0.86 with RF, 0.81 with KNN, 0.67 with SVM and 0.66 for relative change in LD (Fig. 2).

In the test set, the accuracy of the prediction of the 15 patients for classifiers trained with the whole training set on the 3 initial features were: 74.6% for RF, 66.7% for LR, 53% for SVM, 66.7% for KNN and 73.3% for an objective response according to RECIST 1.1. In details,

while 9 (90%) of poor-HR were correctly predicted with RF, 3 (60%) good HR were systematically misclassified in the test set.

Since the best compromise was obtained with the RF classifier, we investigated the impact of adding features in the RF model (Fig. 3). Accuracy and AUROC were not improved in the training cohort and they decreased in the test cohort. In the training cohort, specificity was at its highest with 3 features while sensitivity remained constant. In the test cohort, higher sensitivity and specificity were obtained with 3 features. Figure 4 illustrates the added value of the final RF algorithm for two cases with a stable disease according to RECIST 1.1, one being a poor-HR, the other a good-HR.

The retrospective analysis of the false positive predictions made by the RF model highlighted cases of massively necrotic-hemorrhagic tumors and late-responder profiles (Fig. 5). Quantification of tumor heterogeneity was biased by heterogeneous large blood clots on baseline examination and their changes at early evaluation. Analysis based on other imaging modalities of ‘late-responder’ cases did not provide any clue to predict a good response after 2 cycles, whereas pre-surgical evaluation demonstrated extensive fibro-necrotic changes, strong decrease of DCE-MRI parameters and SUVmax.

DISCUSSION

In this study, we developed and evaluated radiomics models to predict the histological response of STS during NAC that were based on changes on T2-WI from baseline to early evaluation. Overall, our best model was obtained with RF classifiers on 3 relevant features from analysis of STS shape, heterogeneity and surrounding tissue. It performed better than RECIST 1.1 with an accuracy of 88.1% and AUROC of 0.86 at cross-validation and had the highest scores on the independent test cohort. However, those last results highlighted outliers requiring additional characterization.

Performances of our best predictive model were comparable or higher than those found for other imaging biomarkers in literature although we should be careful in making comparisons since different cut-offs may have been used to define a good histological response, different chemotherapy regimens may have been prescribed and imaging may have been performed at different stages in time. Stacchiotti et al. investigated CHOI criteria to predict a pathological very good response defined as <10% viable cells on surgical specimen in a series of 37 patients. They obtained an accuracy of 74.1% (14/22 CHOI partial responders being true good-HR and 6/6 CHOI non-responder being true poor-HR)^{21,22}. In another studies, a

decrease in contrast-enhancement of -30.5% between two MRI with optimized acquisition delay after contrast-agent injection provided an accuracy of 82.8%²³. On a retrospective series of 23 patients, multiparametric assessment combining qualitative evaluation of diffusion imaging and DCE-MRI provided a best AUROC of 0.833²⁴. At early evaluation with ¹⁸F-FDG-PET-CT, a decrease >35% of SUVmax provided an AUROC of 0.83 in a prospective study of 50 patients^{25,26}.

Association between decrease in edema and good response did not surprise us. Surrounding edema is associated with high-grade STS and satellite tumor cells²⁷⁻²⁹. NAC efficacy should logically go with reduced satellite tumor cells and thus a decrease of signal anomalies surrounding STS on MRI. A decrease in tumor cellularity turning into fibro-necrotic tissue could explain a tumor softening leading to changes in shape, towards retraction of its borders. Finally, these fibro-necrotic processes lead to a larger range of signal intensity values within tumors, that is to say a flattening of the SI histogram responsible for change in its entropy.

A careful retrospective analysis of the tumors that were systematically ill classified in our series enabled to identify ‘late-responder’ and ‘massively necrotic STS’ profiles. These last ones are difficult to image and their morphological changes during treatment can be complicated to interpret. Evaluation with RECIST 1.1 is biased as it mostly measures the necrosis and not the changes in viable tumor component. DCE-MRI and diffusion imaging are challenging because viable tissue generally consists in small buds attached to the tumor wall within a large hemorrhagic mass. In our case, ¹⁸F-FDG-PET-CT correctly predicted a good response according to the previously published cut-off of a 35-38% decrease in SUVmax²⁶. These two observations from the test cohort provide insights into next features to add to the future predictive models. Partitioning dataset in independent training and test datasets enabled to have a larger view of the response patterns of STS, and to consider additional imaging features from other advanced imaging modalities for improvement of the future models.

Interestingly, our best models relied on a limited set of features from non-contrast enhanced sequences. Corino et al. also found that only 3 features from diffusion imaging provided the highest accuracy to predict histological grade of STS⁹. The best model to predict lung metastatic relapse of STS according to Vallières et al. relied on 4 texture features¹³. In their studies, adding any other feature to the model did not improve prediction. In a context of controversy about long-term effects of Gadolinium-chelates contrast agents, an imaging work-flow for response evaluation may be considered in which known outliers of the model or patients with an intermediate probability of response could be assessed in a second step with contrast agent injection and advanced imaging modalities such as DCE-MRI, DWI and ¹⁸F-FDG-PET-CT.

Our study has limits. First, this is a retrospective study with a relatively small number of patients. Nevertheless, our series is one of the largest regarding STS and MRI, with uniformly treated patients with the chemotherapy of reference. No epidemiological data was added into the model because none was associated with the tumor response at univariate analysis. Indeed, the population study only included patients who shared all the epidemiological features associated with worse prognosis, namely high-grade, deep- or deep and superficial STS with LD above 5cm³⁰. Beside, if modest, the cohort was significant enough to put a few data aside to form an independent validation set and control our results.

Second, imaging protocols were not designed for radiomics studies. 2D TSE T2-WI was used for features extraction because (i) it was the most commonly acquired sequence, (ii) it provided a large range of morphological changes during treatment, (iii) there was no change in the acquisition parameters during the study period. T2-WI can capture fibrotic and necrotic processes (decreased and increased T2 SI, respectively). T2-WI has already demonstrated good results in textural approaches applied to other tumor types³¹⁻³⁵. Conversely, post-contrast T1-WI sequences showed heterogeneous acquisition protocols in our series: some were 3D gradient recalled echo imaging and others 2D TSE, different fat suppression techniques were used (Dixon method, fat-sat, short TI inversion recovery, subtraction with pre-contrast T1-WI), as well as different contrast agents. Furthermore, the acquisition delay after contrast agent injection was not standardized although it may have a significant effect on changes in tumor heterogeneity quantified on CE-T1-WI. Changes in surrounding edema helped predict response but its assessment could only be qualitative because of non-standardized sequence for its evaluation. Future studies should include automatic and quantitative assessment of edema and its changes, since it was one of the best predictor for the response in the current study. Adding another imaging modalities would have markedly decreased the population study and we made the decision to privilege one informative sequence and an acceptable population study. Nevertheless, this point stresses the urge for a standardized MRI protocol for STS.

Third, post-processing included voxel size standardization - with an acceptable voxel size to preserve the global shape of tumor - and signal intensity normalization. The aim was to limit the inherent bias due to MR acquisition at different stages on different MR-systems and to improve the reliability and the reproducibility of the extracted features. 3D Segmentation was manually performed, slice-by-slice. Automatic and semi-automatic methods were tried before the study with disappointing results as compared to those obtained by the expert radiologist from a sarcoma reference center.

Fourth, we decided to limit the number of extracted textural features, despite the fact that several others could have been calculated from fractal analysis, wavelet, and other matrices³⁶. Therefore, we limited the risk of finding relevant features by chance and facilitated the understanding of our results. Those we calculated are widely used and can be easily found in open libraries³⁷. Due to the relatively small population study, we did not apply deep-learning purposely and focused on time-tested classifiers. Finally, one could question the outcome. The histological response is routinely used as an intermediate evaluator reflecting immediate efficacy of NAC and patient prognosis¹⁶. Nonetheless, it is a semi-quantitative assessment, with possible subjectivity and sample bias. Ultimately, our goal is to build predictive models for survival, but only 41 patients in this series have a follow-up of more than 2 years and 26 of more than 5 years.

To conclude, our preliminary results indicate that T2-based delta-radiomics approach applied to STS in the neoadjuvant setting is feasible, provides valuable information to predict response after only 2 cycles and improves evaluation compared to RECIST 1.1. Optimization of the model is still needed with the study of larger cohorts and inclusion of other categories of features, other imaging modalities and other ‘-omics’ criteria.

TABLES :**TABLE 1.** Epidemiologic characteristics

Characteristics		Patients (n=65)
Gender	Male	38 (58.5)
	Female	27 (41.5)
Age at diagnosis (y), mean $\pm$ sd		57.9 $\pm$ 12.8
Histotype	Undifferentiated sarcoma ¹	33 (50.8)
	Muscular sarcoma ²	13 (20)
	M/RC liposarcoma ³	5 (7.7)
	Other liposarcoma ⁴	6 (9.2)
	Synovial sarcoma	7 (10.8)
	MPNST	1 (1.5)
Location	Trunk wall	12 (18.5)
	Pelvic Girdle	2 (3.1)
	Shoulder Girdle	6 (9.2)
	Upper limb	7 (10.8)
	Lower limb	38 (58.5)
Depth	Superficial	4 (6.2)
	Deep	61 (93.8)
LD at baseline (mm), mean $\pm$ sd		119 $\pm$ 56
Nb cycles	4 cycles	22 (33.8)
	5 or 6 cycles	43 (66.2)

LD indicates longest diameter, sd indicates standard deviation, MPNST indicates malignant peripheral nerve sheath tumor.

Data are numbers of patients with percentages in parentheses, except for age and LD.

¹ : myxofibrosarcoma or undifferentiated sarcoma ;

² : leiomyosarcoma and rhabdomyosarcoma ;

³ : myxoid/round cells liposarcoma ;

⁴ : pleomorphic or dedifferentiated liposarcoma.

TABLE 2. Association between demographic and semantic radiological features and histological response.

Variables	Good_HR	Poor_HR	p-value
Baseline clinico-radiological features			
Gender			
Male	11 (68.8)	27 (55.1)	0.393
Female	5 (21.2)	22 (44.9)	
Age at diagnosis (y)	58.8 ± 11.4	57.6 ± 13.3	0.873
Histotype			
Undifferentiated sarcoma ¹	10 (62.5)	23 (46.9)	0.257
Muscular sarcoma ²	5 (21.2)	8 (16.3)	
M/RC liposarcoma ³	1 (6.3)	4 (8.2)	
Other liposarcoma ⁴	0 (0)	6 (12.2)	
Synovial sarcoma	0 (0)	7 (14.3)	
MPNST	0 (0)	1 (2.1)	
Location			
Trunk wall	2 (12.5)	10 (20.4)	0.146
Pelvic Girdle	2 (12.5)	0 (0)	
Shoulder Girdle	1 (6.3)	5 (10.2)	
Upper limb	2 (12.5)	5 (10.2)	
Lower limb	9 (56.2)	29 (59.2)	
Depth			
Superficial	1 (6.3)	3 (6.1)	1.000
Deep	15 (93.7)	46 (93.9)	
Nb cycles			
4 cycles	11 (68.8)	32 (65.3)	1.000
5 or 6 cycles	5 (21.2)	17 (34.7)	
LD on MRI_0 (mm)	146 (66)	110 (51)	0.038 *
MRI_0 to MRI_1			
Change in LD (%)	-11.2 ± 20.8	2.9 ± 19.5	0.027 *
RECIST 1.1			
Complete Response	0 (0)	0 (0)	0.112
Partial Response	3 (18.8)	3 (6.1%)	
Stable Disease	13 (81.2)	39 (79.6)	
Progressive Disease	0 (0)	7 (14.3)	
Objective Response			
Yes	3 (18.8)	3 (6.1)	0.154
No	13 (81.2)	46 (93.9)	
Δ_Margin_definition [§]			
Well- or better limited	5 (21.2)	9 (20)	0.490
stable or worst	11 (68.8)	36 (80)	
Δ_Edema			
None or decrease	12 (75)	15 (30.6)	0.003 **
Stable or increase	4 (25)	34 (69.4)	
Δ_Peritumoral enhancement [§]			
None or decrease	12 (80)	24 (57.1)	0.134
Stable or increase	3 (20)	18 (42.9)	
Fibro-Necrotic Changes			
No	2 (21.2)	14 (25.6)	0.430
< 50% tumor volume	9 (56.2)	23 (46.9)	
≥ 50% tumor volume	5 (31.3)	12 (24.5)	

LD indicates longest diameter, sd indicates standard deviation. MPNST indicates malignant peripheral nerve sheath tumor.

Data are numbers of patients with percentages in parentheses, except for age, LD and change in LD.

¹ : myxofibrosarcoma or undifferentiated sarcoma ;

² : leiomyosarcoma and rhabdomyosarcoma ;

³ : myxoid/round cells liposarcoma ;

⁴ : pleomorphic or dedifferentiated liposarcoma.

§: 8 patients had missing values for Δ_Peritumoral_enhancement and 4 for Δ_Margin_definition due to defective MR protocol (incomplete acquisition of edema on post contrast T1-WI, different acquisition plan on MRI_0 and MRI_1). * : $p \leq 0.05$; ** : $p \leq 0.005$.

TABLE 5. Diagnostic performance of the classifiers on the 3 selected features for training and test cohorts (respectively cross-validation and final test steps).

Classifiers	Accuracy	AUROC	Sensitivity	Specificity	PPV	NPV	Train Score
Training Cohort							
Random Forest	88.1 (87.6-88.5)	0.86 (0.86-0.87)	94.1 (93.8-94.4)	66.3 (64.7-67.8)	90.9 (90.5-91.2)	76.2 (75.0-77.3)	0.98
K-nearest neighbors	80.5 (80.2-80.7)	0.81 (0.81-0.82)	97.3 (97.1-97.4)	20.5 (19.5-21.4)	81.3 (81.1-81.5)	66.9 (65.1-68.8)	1.00
Support Vector Machines	75.2 (74.5-75.8)	0.67 (0.66-0.68)	85.4 (84.7-86.2)	37.9 (36.5-39.3)	83.0 (82.6-83.3)	42.8 (41.3-44.4)	0.96
Logistic Regression	85.8 (85.6-86.0)	0.87 (0.86-0.87)	94.8 (94.8-94.9)	53.2 (52.5-53.9)	87.8 (87.6-87.9)	74.4 (74.1-74.7)	0.87
RECIST 1.1 [§]	76.0	0.66	57.0	90.9	66.7	21.3	—
Test Cohort							
Random Forest	74.6 (73.7-75.5)	0.63 (0.62-0.63)	98.0 (97.2-98.8)	27.8 (25.9-29.7)	73.1 (72.6-73.7)	90.8 (87.2-94.5)	0.98
K-nearest neighbours	66.7	0.53	100.0	0.0	66.7	0.0	1.00
Support Vector Machines	53.3	0.52	80.0	0.0	61.5	0.0	0.98
Logistic Regression	66.7	0.46	90.0	20.0	69.2	50.0	0.86
RECIST 1.1 [§]	73.3	0.72	90.0	40.0	75.0	66.6	—

AUROC indicates area under the ROC curve, PPV indicates positive predictive value, NPV indicates negative predictive value.

Accuracy, sensitivity, specificity, PPV and NPV are given in percentage with 95% confidence interval in parentheses.

[§] Statistics are given for RECIST 1.1 in an objective response setting, that is to say ‘complete response or partial response’ vs. ‘stable disease or progressive disease’. AUROC corresponded to AUROC of relative change in longest diameter, on which RECIST 1.1 status is based.

FIGURE LEGENDS

FIGURE 1: Radiomics pipeline. (a) First step consisted in MRI post-processing, including resampling (with a bi-linear interpolation), bias removal (N4) and normalization of signal intensities (with histogram-matching). The volume of interest was manually segmented, slice by slice, and then propagated on post-processed images, enabling the extraction of histogram-based, texture and shape features (b). This process was applied on baseline MRI and MRI after 2 cycles of neoadjuvant chemotherapy providing delta-radiomics features (Δ _features), which were rescaled (standard scaling). (c) Statistical method. In step 1, the whole data set was partitioned into a ‘Training Cohort’ and a ‘Test Cohort’. In step 2, the ‘Training cohort’ was used to build the model. It was based on a 10-fold cross-validation that consisted in separating the 50 patients into 10 blocks of 5 patients. For each of the 10 combinations, the classifier was trained on the subset of 9 blocks (blue squares), then validated on the remaining block (in light orange). At the end of the cross-validation, each block has been used once for validation (*). This whole process was repeated with different tuning parameters proper to each type of classifier (: hyperparameters, *Supplemental Data*) and different methods for features selection and preprocessing, until obtaining a model with the highest accuracy and area under the ROC curve (AUROC). Those optimal metrics are shown in the cross-validation section of the results. In step 3, a model with the optimal combination of parameters was fitted on the whole training cohort. This final model was tested on the independent test cohort (dark orange) and its diagnostic performance (accuracy, AUROC, PPV, NPV, specificity, sensitivity, negative/predictive value) was calculated.

FIGURE 2: ROC curves of random forest model, logistic regression model and relative change in longest diameter from baseline to post-2 cycles of chemotherapy (% Change_LD) at cross-validation. Random forest and logistic regression were based on the optimal selection of features (Change in surrounding edema, change in histogram-entropy, change in Elongation). For each classifier, the individual scores of each sample from all folds are sorted together into a single ROC curve and then averaged across the 100 repetitions.

FIGURE 3. Accuracy, AUROC, sensitivity and specificity of the random forest algorithm as functions of the numbers of features included in the model. These statistic metrics were calculated in the training cohort (a) and the test cohort (b). Features were added in the ascending order of their p-value (descending order of statistical significance) as listed in Table 1 and 2. The grey dashed vertical line emphasizes the initially selected 3-features model (changes in edema, histogram_entropy and elongation from baseline to post-2 cycles evaluation).

FIGURE 4: Added value of final random forest (RF) model for early response prediction.

(a) 76 years-old male presented with a deep-seated grade III pleomorphic rhabdomyosarcoma of the shoulder. After 2 cycles of chemotherapy, the tumor was stable according to RECIST 1.1 criteria, but it demonstrated an increase of its surrounding edema (white arrows), stability of its shape and stable histogram entropy. Hence, the final RF model predicted a poor histological response that was confirmed on surgical specimen (70% residual viable cells).

(b) 50 years-old male presented with a deep-seated grade III undifferentiated pleomorphic sarcoma of the popliteal region. After 2 cycles of chemotherapy, the tumor was stable according to RECIST 1.1 criteria. Surrounding edema markedly decreased (white arrow heads) with a retraction of its shape on 3D reconstruction and a decreased entropy on normalized histogram. The final RF model predicted a good response that was confirmed on surgical specimen (5% residual viable cells).

T2: T2-weighted imaging, FS: fat-sat, PD: proton-density weighted-imaging

FIGURE 5: Outliers patients who were misclassified as poor responders by the model. (a) Example of massively necrotic tumor at baseline: 52 years-old male presented with deep-seated grade III undifferentiated pleomorphic sarcoma of the left thigh. Blood clots and fibrinous septa were mixed with necrosis (white arrow), only small buds of tumor were seen against tumor wall. Therefore, changes in tumor heterogeneity were mostly due to change in structure and signal of the necrotic-hemorrhagic compartment. (b) This patient benefited from a ^{18}F -FDG-PET-CT at baseline and after two cycles showing a strong decrease of SUVmax (8.16 to 3.94, -51.7%) suggestive of chemotherapy efficacy. (c) Example of a ‘late responder’ profile: 66 years-old male presented with a deep-seated grade III pleomorphic rhabdomyosarcoma of the abdominal wall. No obvious change was seen by

visual assessment at early evaluation. (d) ^{18}F -FDG-PET-CT demonstrated a slight paradoxical increase of SUVmax (22.34 to 24.32) although the patient was a good histological responder after 4 additional cycles of chemotherapy.

T2-WI: T2 weighted imaging; Gd+ FS T1-WI: Fat-Sat T1 weighted imaging after Gadolinium-chelates injection.
