ABSTRACT

BACKGROUND: Possible mechanisms of left axis deviation (LAD) in the setting of left bundle branch block (LBBB) include differences in cardiac electrophysiology, structure, or anatomical axis.

OBJECTIVES: We sought to clarify the mechanism(s) responsible for LAD in patients with LBBB.

METHODS: Twenty-nine patients with non-ischemic cardiomyopathies and LBBB underwent non-invasive electrocardiographic mapping (ECGi), cardiac computed tomography, and magnetic resonance imaging in order to define ventricular electrical activation, characterize cardiac structure, and determine the heart anatomical axis.

RESULTS: Sixteen patients had a normal QRS axis (NA, mean axis: $8\pm 23^\circ$) whereas 13 patients had LAD (mean axis: $-48\pm 13^\circ$, $p<0.001$). Total activation times were longer in the LAD group (112 ± 25 vs 91 ± 14 ms, $p=0.01$) due to delayed activation of the basal anterolateral region (107 ± 10 vs 81 ± 17 ms, $p<0.001$). Left ventricular (LV) activation in patients with LAD was from apex-to-base, contrasting with a circumferential pattern of activation in patients with NA. The apex-to-base delay was therefore longer in the LA group (95 ± 13 vs 64 ± 21 ms, $p<0.001$) and correlated with the QRS frontal axis ($R^2=0.67$, $p<0.001$). Both groups were comparable in LV end diastolic volume (295 ± 84 vs LAD: 310 ± 91 ml; $p=0.69$), LV mass (177 ± 33 vs LAD: 180 ± 37 g, $p=0.83$) and anatomical axis.

CONCLUSION: Left axis deviation in left bundle branch block appears to be due to electrophysiological abnormalities rather than structural factors or the cardiac anatomical axis.

Key Words: left bundle branch block, QRS axis, left axis deviation, electrical mapping, computer modeling

INTRODUCTION

Left bundle branch block (LBBB) is an important pathophysiologic determinant in patients with heart failure and is readily diagnosed on standard 12-lead surface ECGs. Although the alterations in ventricular depolarization produced by LBBB have been largely characterized,^{1,2} why certain patients with LBBB exhibit a leftward QRS axis (between -30° and -90°) instead of a normal axis (NA, between -30° and 90°) remains unknown. Left axis deviation (LAD) could be due to differences in regional electrical activation, in left ventricular (LV) structure, or simply in the anatomical axis of the heart. A comprehensive electroanatomic evaluation of this ECG finding could clarify its mechanism and clinical significance. We therefore sought to test potential electrophysiologic, structural, and anatomic explanations for LAD in a cohort of patients with non-ischemic cardiomyopathy and LBBB undergoing cardiac resynchronization therapy (CRT) device implantation.

METHODS

This study conformed to the principles outlined in the Declaration of Helsinki on research in human subjects and was approved by the Bordeaux Centre Hospitalier Universitaire (CHU) ethics committee. All patients provided written consent to participate in the study.

Study population

Twenty-nine patients with non-ischemic dilated cardiomyopathy undergoing CRT implantation were selected. All patients met the following criteria: (1) New York Heart Association (NYHA) functional class $\geq$ II despite optimal medical therapy; (2) LV ejection fraction (LVEF) $\leq$ 35% during sinus rhythm; and (3) LBBB on 12-lead ECG defined as an intrinsic QRS duration of $\geq$ 130ms, broad notched or slurred R wave in leads I, aVL, V5, and V6, and absent q waves in leads I, V5, and V6.³ A subset of the study population has been described previously in a separate study.⁴ LAD was defined as a QRS axis of $<-30^{\circ}$ in the frontal plane on 12-lead ECG.

Noninvasive mapping of electrical activation

Ventricular epicardial activation maps were acquired during intrinsic activation in sinus rhythm and right ventricular apical pacing (RVAP) with an atrioventricular delay of 80ms using a noninvasive, high-resolution electrocardiographic imaging (ECGi) system (ECVUE, CardioInsight Technologies Inc, Cleveland, OH). All maps were obtained within 72 hours post-CRT implantation. Briefly, body surface potentials were recorded by 252 electrodes around the entire torso. Next, a thoracic computed tomography scan was performed with the electrodes attached to the patient. The two exams were then combined and processed to reconstruct 1500 epicardial unipolar electrograms. Ventricular activation times were measured from the onset of the QRS duration (intrinsic conduction) or the pacing spike (RVAP) to the maximal negative slope of each unipolar electrogram. For comparison purposes between intrinsic and RVAP, all the subsequent calculations used the first ventricular activation as a reference. Activation times were exported to MATLAB (MathWorks, Natick, MA) to calculate mean activation times for 24 epicardial segments (basal, mid, and apical anterior, anterolateral, inferolateral, and inferior segments for both ventricles). Total activation time (TAT) was defined as the time from the earliest to the latest site of ventricular activation, excluding the first and last 5% of activation. Ventricular electrical uncoupling (VEU), a marker of interventricular dyssynchrony, was defined as the difference between mean LV and RV activation times in spontaneous rhythm.⁵ The apex-to-base delay was defined as the time from RV anteroapical activation to LV basal anterolateral activation in spontaneous rhythm. Finally, bullseye plots of the average electrical activation per segment in sinus rhythm and during RVAP were plotted for NA and LAD groups.

Anatomic calibration

The position of the heart within the torso was defined by its anatomical axis in three dimensions, calculated from its spatial coordinates extracted from ECGi and processed in MATLAB. Automated rotations were performed in sagittal, frontal, and transversal planes until a standardized position was achieved with the mitral valve was on top, the apex on the bottom, the right ventricular (RV) free wall on the right side, and the LV free wall on the left side. The amount of rotations required to achieve this “calibrated” position were measured and compared to examine the impact of the heart’s anatomical axis on the QRS axis.

Computer simulation of the impact of altering regional activation on the surface ECG

To explore the influence of altering electrical activation patterns while keeping the cardiac structure and position constant, we used an ECG simulator (ECGSIM v3.0.1, Nijmegen, The Netherlands). ECGSIM is an interactive computer simulation program that allows users to alter ventricular depolarization times and to study its effects on the surface ECG.⁶ The averaged electrical activation times per segments of each group were used as an input for the two simulations.

Cardiac magnetic resonance (CMR) imaging

CMR was used to investigate the potential influence of structural heart disease on QRS axis in a subset of patients. CMR studies were acquired using a 1.5-T system (Magnetom Avanto, Siemens Medical Systems, Erlangen, Germany) equipped with a 32-channel cardiac coil. Cine imaging was performed at a temporal resolution of 40 milliseconds. A stack of 12 short axis slices was acquired, evenly spaced over the entire LV from base to apex. Long axis slices of the LV were also acquired (four-, three-, and two-chamber views). Delayed enhanced imaging was performed 10–12 minutes after administering 0.2 mmol/kg of intravenous gadoterate meglumine. LV mass and volume were quantified on short axis slices using CMR42 software (Circle Cardiovascular Imaging Inc., Calgary, AB, Canada).

CRT device implantation

All patients underwent implantation of a CRT device. Although the RV lead was generally implanted at the RV apex, the position of the LV lead was not prespecified. The final LV pacing position was determined by coronary venous anatomy, lead stability, pacing thresholds, and assessment of phrenic nerve capture.

Statistical Analysis

Categorical variables are expressed as absolute numbers and percentages; continuous variables are expressed as mean $\pm$ SD. Student t or Welch tests were used to compare mean values, as appropriate. Percentages were compared by either chi square or Fisher tests. Associations between selected parameters and the QRS axis were determined using linear regression. All analyses were performed using RStudio (version 1.2.5033). P-values <0.05 were considered statistically significant.

RESULTS

Patient characteristics and measures of electrical dyssynchrony

Twenty-five patients (86%) had idiopathic dilated cardiomyopathy, 3 (10%) had valvular cardiomyopathy, and 1 (3%) had cardiomyopathy secondary to anthracycline cardiotoxicity. All 29 patients underwent noninvasive ECGi in sinus rhythm, of which 19 also had ECGi performed during RVAP and 22 also underwent CMR imaging with late gadolinium enhancement (LGE).

Thirteen patients had LBBB with LAD (mean QRS axis of $-48 \pm 13^\circ$) whereas 16 had NA (mean QRS axis of $8 \pm 23^\circ$, $p < 0.001$). Clinical characteristics are detailed in **Table 1**. Patients with LAD had similar age, height, weight, LVEF, medical treatment as compared with patients with NA. Patients with LAD had a non-significant longer QRS durations (166 ± 16 vs 160 ± 11 ms, $p = 0.21$), had longer TATs (112 ± 25 vs 91 ± 14 ms, $p = 0.01$), apex-to-base time delays (95 ± 13 vs 64 ± 21 ms, $p < 0.001$) and VEU (76 ± 11 ms vs 65 ± 8 ms, $p = 0.007$). The distribution of these parameters is shown in **Figure 1**.

Activation patterns during sinus rhythm

Representative 3D electrical intrinsic activation maps of patients with LBBB and NA versus LAD are shown in **Figure 2**. RV activation patterns were similar for both groups, with breakthrough activation from its free wall followed by circumferential spreading toward the LV. In contrast, LV activation differed in terms of patterns and latest activated area. LBBB with NA was associated with circumferential LV activation with the latest activation seen at the mid lateral LV wall. In contrast, LBBB with LAD demonstrated the latest activation at the basal lateral LV wall, resulting in an apex-to-base activation pattern. In fact, the apex-to-base activation delay correlated significantly with QRS axis ($R^2 = 0.67$, $p < 0.001$), with a higher gradient associated with a more leftward axis (**Figure 3**). As a consequence, activation of the LV basal segments was more delayed in the LAD group: basal anterolateral (107 ± 10 vs 81 ± 17 ms, $p < 0.001$), basal inferolateral (100 ± 11 vs 84 ± 20 ms, $p = 0.009$), and basal anterior (53 ± 17 vs 38 ± 17 ms, $p = 0.03$). An overview of regional electrical activation is presented in **Supplementary Table 1**. Bullseye plots of mean activation times are presented in **Figure 4** (left panel).

Activation patterns during RVAP

Among the 19 patients who underwent ECGi mapping during RVAP, 13 had NA (68%) and 6 had LAD (32%). Bullseye plots of mean activation times per group are shown in **Figure 4**. As expected, RV breakthrough was apical followed by RV basal activation. The site of earliest LV activation was also apical, followed by an activation front proceeding from apex-to-base. TATs were similar during sinus rhythm and RVAP in patients with NA (95 ± 10 vs RVAP: 90 ± 15 ms, $p=0.28$) and LAD (101 ± 16 vs RVAP: 101 ± 25 ms, $p=0.97$). However, in patients with LAD, basal LV activation was again delayed in comparison with NA patients: basal anterolateral (108 ± 16 vs 89 ± 17 ms, $p=0.03$), basal anterior (95 ± 29 vs 64 ± 28 ms, $p=0.04$), basal inferolateral region (98 ± 15 vs 85 ± 13 , $p=0.10$). An overview of regional electrical activation is presented in **Supplementary Table 2**.

Computer simulations

The mean regional activation times from patients with NA were entered into ECGSIM. As shown in **Figure 5**, this resulted in a typical LBBB on the ECG with a NA (-14°). When the activation times of the LV base free wall were delayed in accordance with the mean regional activation times from patients with LAD, the QRS axis moved leftward (-38°), in keeping with clinical observations and findings on ECGi in the LAD group.

Structural and anatomical differences

Of the 22 patients who underwent CMR imaging, 13 had NA (59%) and 9 had LAD (41%). There were no significant differences between the two groups in terms of LVEF (NA: $22\pm 9\%$ vs LAD: $19\pm 7\%$, $p=0.42$), indexed LV end diastolic volume (NA: 154 ± 46 vs LAD: 171 ± 47 ml/m², $p=0.69$), or indexed LV mass (NA: 92 ± 20 vs LAD: 99 ± 18 g/m², $p=0.40$). CMR imaging results are summarized in **Table 2**. Myocardial fibrosis was detected in three patients (10%), all of whom had NA ($p=0.23$). Among the 29 patients there were no significant differences in the heart's orientation within the torso, with similar degrees of rotation required in all planes in both NA and LAD groups to reach the standard calibrated position (sagittal: $53\pm 11^\circ$ vs $53\pm 9^\circ$, $p=0.90$; frontal: $-8\pm 6^\circ$ vs $-11\pm 7^\circ$, $p=0.27$; transverse: $-52\pm 10^\circ$ vs $-55\pm 11^\circ$, $p=0.51$) (**Figure 6**).

DISCUSSION

We examined whether the QRS axis in patients with heart failure and LBBB is determined by electrophysiologic, structural, or anatomic characteristics. The results of our study support a purely electrophysiologic explanation for LAD in patients with LBBB, with no discernible associations of structural characteristics (cardiac size, LV dimensions, or LV mass) or cardiac anatomical axis with the QRS axis.

LAD is an electrical phenomenon

LV activation in the setting of LBBB has been widely described in the literature as being circumferential, spreading from the RV free wall to the LV lateral wall.^{5,7} However, important differences in activation exist among patients with LBBB based on their QRS axis. Patients with LBBB plus LAD exhibit an apex-to-base activation sequence with a marked delay in activation of the LV base. This added delay deviates electrical forces, resulting in a leftward QRS axis – an activation sequence that can be mimicked by RVAP.⁸ This explanation is bolstered by the strong correlation between the apex-to-base gradient and QRS axis, with a higher gradient being associated with a more leftward axis. The ECGSIM simulations further support an electrophysiologic etiology for LAD as anatomical and structural factors were not altered in those models.

Our results are in line with body surface mapping data from patients with LBBB and NA or LAD published by Sohi et al.⁹ In their study, the electrical force produced by LV activation remained anterior throughout depolarization in patients with NA, but moved toward the left shoulder and left upper back in patients with LAD. Based on this observation, the authors speculated that in LBBB with LAD a further selective slowing of depolarization existed anterobasally with the terminal positive potentials directed posterosuperiorly. Our data from advanced mapping technologies support this hypothesis, while also accounting for the heart's position in the torso via computed tomography and cardiac structural factors via CMR.

Mechanisms of LAD in LBBB

Several hypotheses have been proposed to explain mechanisms of LAD in patients with LBBB. In 1960, Rosenbaum classified LBBB into predivisional and divisional types.¹⁰

Predivisional LBBB referred to a conduction block in the main stem, while divisional LBBB referred to an interruption within divisional branches. Many authors postulated that LBBB with LAD was the result of a two-level block: a divisional left anterior hemiblock in addition to a predivisional LBBB.^{11–13} Cannom et al were the first to provide empirical support for this theory by demonstrating a leftward shift in mean QRS axis following an atrial extrastimulus in six patients with LBBB.¹³ Several years later, Gressard similarly used an electrophysiologic approach to explain axis differences in patients with LBBB. He observed the same response to atrial extrastimulus and concluded that LBBB with NA was due to slowed but persistent conduction in both anterior and posterior rami of the left bundle. In contrast, in LBBB with LAD, conduction was blocked in the anterior ramus.¹² However, in the study by Cannom and al, the QRS axis deviation was relatively modest, not deviating past -30° except in one patient. Moreover, Rosenbaum et al found that when a left anterior hemiblock is produced experimentally, further sectioning of the trunk of the branch results in disappearance of the marked QRS LAD.¹⁴ Furthermore, ECGs of patients with intermittent LBBB have shown that the QRS axis with LBBB often does not correspond to the QRS axis without LBBB, therefore underlying left anterior hemiblock would not account for LAD during LBBB in most patients.^{15–17} Finally, Riedlbauchová et al recently performed endocardial electroanatomic mapping in 11 patients with LBBB and did not observe early activation of the left anterior or posterior fascicles regions in any patient. Instead, the LV was consistently activated through transmural conduction.¹⁸

Our mapping study does not support the hypothesis of residual anterograde Purkinje conduction as the etiology for LAD in patients with LBBB. In patients with NA, activation during spontaneous rhythm and during RVAP differed in terms of pattern but not duration. During RVAP ventricular activation is not dependent on the Purkinje network, but depends entirely on transmural conduction. Thus, if the Purkinje network was involved in LV activation during sinus rhythm in patients with LBBB and NA, LV activation times would be expected to be shorter in sinus rhythm than during RVAP. Moreover, the persistently delayed activation of the basal anterior and basal lateral regions of the LV in patients with LBBB and LAD during RVAP favors the existence of additional conduction disturbances in these patients. Thus, LAD in patients with LBBB appears to be due to additional

transmyocardial conduction disturbances that result in delayed activation of the basal anterior and basal lateral regions of the LV.

Another proposed theory was that LV enlargement was the driver of QRS axis deviation in patients with LBBB.^{15,19} Our results do not support this explanation as we found no relation between the QRS axis and cardiac structural characteristics (cardiac size, LV dilatation, or LV wall mass) or the anatomical axis of the heart. Our findings align well with a prospective study by Das et al that did not find a correlation between the QRS axis and LVEF in 300 consecutive patients with LBBB.²⁰ Although dilated cardiomyopathy is commonly found in patients with LBBB and LAD, LV dilatation alone does not seem to adequately account for the LAD. However, it is possible that LAD is a marker of more advanced electrophysiological remodeling. Our findings may prove useful to interpret ongoing investigations of LV septal pacing and conduction system pacing.²¹ These evolving technologies rely on underlying electrophysiological substrates in the LV which may thus vary between LBBB patients.

Characteristics of the signal

When using ECGi to investigate axial differences in the frontal plane, it is important to consider potential differences between endocardial and epicardial cardiac layers. As compared to frontal bipolar leads, unipolar chest electrodes used for the surface ECG and ECGi are subjected to a larger contribution of epicardial signals, as they are in closer proximity with the epicardium. However, the recorded signal is also composed by transmembrane potential differences in intramural and endocardial cardiac layers and therefore rather reflects a net activation of the cardiac wall.²² The extent to which non-contact mapping represents local activation has been investigated by Thiagalingam et al in murine ventricles. They compared a non-contact mapping system (EnSite) with a grid of 50-60 plunge needles, each holding four contact electrodes recording from the endocardium, two intramural sites, and the epicardium. Noncontact electrograms correlated equally well in morphology and timing across all layers confirming that noncontact electrograms are a composed signal rather than a local measurement.²³ On the other hand, while the abnormalities which cause LBBB originate in the endocardium, it is the net activation of all cardiomyocytes which give rise to the frontal plane axis. While the agreements between ECGi and frontal axis ECG are not perfect, the non-invasive single-beat ECGi mapping system

remains the tool of choice for investigating the etiology of ECG axis deviation in LBBB patients.

Study limitations

Previous validation studies of ECGi have shown that agreement of non-invasive electrocardiographic mapping and contact mapping is limited. However, it is important to note that the agreement was poor for narrow QRS patterns but that there was good correlation for wide QRS patterns.²⁴ Moreover, our results were highly consistent for the two groups. Besides, our study only evaluated patients with reduced ejection fraction. Whether our findings hold true in patients with LBBB and preserved ejection fraction remains to be investigated.

CONCLUSION

LAD in patients with heart failure and LBBB is due to additional transmural conduction disturbances that result in markedly delayed activation of the basal anterolateral regions of the LV wall, and are not related to the anatomical axis of the heart or to cardiac structural factors.

Figure 4: Ventricular activation times of all normal axis (top) and leftward axis deviation (bottom) averaged per segment during sinus rhythm (left) and right ventricular apical pacing (RVAP, right).

Figure 5. Simulated epicardial activation map of normal axis LBBB (top panel) and left axis LBBB (bottom panel). LBBB = left bundle branch block.

Figure 6. Representation of baseline and calibrated position of the heart within the torso. **Left panel:** Baseline anatomical position of the heart in the torso. Each point represents one of the 252 body surface electrodes. Direction of rotation for each plane is shown. **Right panel:** The heart in calibrated (standard) position after rotations in sagittal (X), frontal (Y) and transverse (Z) planes.
