Rapport de recherche n° 2800 — Février 1996 — 19 pages

**Abstract:** In this paper we build upon results of Padua and Wolfe [8], who introduce two graph transformations to eliminate anti and output dependences. We first give a unified framework for such transformations. Then, given a loop nest, we aim at determining which statements should be transformed so as to break artificial cycles involving anti or output dependences. The problem of finding the minimum number of statements to be transformed is shown to be NP-complete in the strong sense, and we propose two efficient heuristics.

**Key-words:** node splitting, anti dependences, output dependences, dependence graph, NP-completeness, heuristics.

# Sur l'élimination des anti-dépendances et des dépendances de sortie

**Résumé :** Nous unifions deux transformations de graphe de dépendances introduites par Padua et Wolfe [8] dans le but d'éliminer les anti dépendances et les dépendances de sortie. Etant donné un nid de boucles, notre but est de déterminer quelles instructions doivent être transformées pour casser les cycles artificiels contenant des anti dépendances ou des dépendances de sortie. Nous montrons que trouver le minimum d'instructions à transformer est un problème NP-complet au sens fort, et nous proposons deux heuristiques.

**Mots-clé :** anti dépendances, dépendances de sortie, graphe de dépendance, NP-complétude, heuristiques.

# 1 Introduction

Flow dependences are the only “true” dependences of a program. Anti dependences and output dependences are due to storage re-use and can be eliminated at the price of more memory usage. Removing anti and output dependences may prove very useful to break data dependence cycles and thereby enabling vectorization and/or improving parallelization.

Many papers have been devoted to the problem of eliminating anti and output dependences. Proposed methods include “array data flow analysis” [4, 7], “array privatization” [6], “variable expansion” [3], “variable renaming” [8] and “node splitting” [8]. See the survey papers of Banerjee, Eigenmann, Nicolau and Padua [2] and Bacon, Graham and Sharp [1], as well as the books of Wolfe [14] and Zima [15], for further references.

In this paper we build upon results of Padua and Wolfe [8], who introduce two graph transformations to eliminate anti and output dependences. We first give a unified framework for such transformations in Section 2. Then, given a loop nest, we aim at determining which statements should be transformed so as to break artificial cycles involving anti or output dependences. The problem of finding the minimum number of statements to be transformed is shown to be difficult: in Section 3, we prove it NP-complete in the strong sense. This justifies the introduction of heuristics in Section 4. Finally, we give some conclusions in Section 5.

## 2 Graph transformations

### 2.1 Two well-known elementary transformations

Padua and Wolfe [8] propose two transformations to break data dependence cycles in the presence of anti or output dependences. These transformations are best illustrated with the original examples of their paper.

#### Anti dependences

Consider the following loop, denoted as  $L_1$ :

```
for  $i := 1$  to  $N$  do
   $S_1: a(i) := b(i) + c(i)$ 
   $S_2: d(i) := (a(i) + a(i + 1))/2$ 
```

There is a flow dependence from  $S_1$  to  $S_2$  because  $S_1$  writes  $a(i)$  and  $S_2$  uses it immediately after. There is also an anti dependence from  $S_2$  to  $S_1$  because  $a(i + 1)$  must be read in  $S_2$  before being written in  $S_1$  at the next iteration. As a consequence, there is a data dependence cycle, as illustrated<sup>1</sup> in Figure 1.

Figure 1: Dependence graph of loop nest  $L_1$  after transformation.

The cycle can be broken by inserting a new assignment to a compiler temporary array as follows:

---

<sup>1</sup>In all figures, flow, anti and output dependence edges are labeled with a “ $f$ ”, a “ $a$ ” and a “ $o$ ” respectively.

```

for  $i := 1$  to  $N$  do
   $S'_2$ :  $temp(i) := a(i + 1)$ 
   $S_1$ :  $a(i) := b(i) + c(i)$ 
   $S_2$ :  $d(i) := (a(i) + temp(i))/2$ 

```

There is now an extra dependence (the flow of the temporary from  $S'_2$  to  $S_2$ ) but the new dependence graph has no cycle (see Figure 2). Therefore the new loop can be directly vectorized:

```

 $S'_2$ :  $temp(1 : N) := a(2 : N + 1)$ 
 $S_1$ :  $a(1 : N) := b(1 : N) + c(1 : N)$ 
 $S_2$ :  $d(1 : N) := (a(1 : N) + temp(1 : N))/2$ 

```

Figure 2: Dependence graph of loop nest  $L_1$  after transformation.

## Output dependences

In the presence of a data dependence cycle due to an output dependence, a similar transformation can be performed. Consider the following loop, denoted as  $L_2$ :

```

for  $i := 1$  to  $N$  do
   $S_1$ :  $a(i) := b(i) + c(i)$ 
   $S_2$ :  $a(i + 1) := a(i) + 2 \times d(i)$ 

```

There is an output dependence from  $S_2$  to  $S_1$  because  $a(i + 1)$  is written in  $S_2$  before being re-written in  $S_1$  at the next iteration. We still have a flow dependence from  $S_1$  to  $S_2$  because of  $a(i)$ , hence the dependence graph of Figure 3. Now, adding a temporary array leads to the following loop:

```

for  $i := 1$  to  $N$  do
   $S'_1$ :  $temp(i) := b(i) + c(i)$ 
   $S_2$ :  $a(i + 1) := temp(i) + 2 \times d(i)$ 
   $S_1$ :  $a(i) := temp(i)$ 

```

Figure 3: Dependence graph of loop nest  $L_2$ .

The new loop has no cycles (see Figure 4) and therefore can be vectorized.

To summarize this section, we see that both transformations have broken a cycle in the dependence graph, thereby enabling vectorization and/or improving parallelization. Of course the price to pay is an increase in the memory requirements. In both cases, we have used an extra temporary array. In Section 2.2, we give a unified framework for generalizing Padua and Wolfe's transformations.

Figure 4: Dependence graph of loop nest  $L_2$  after transformation.

## 2.2 A unified transformation

We unify the two transformations of the previous section in a general setting. Then we identify the transformations induced on the dependence graph, and we formally state the problem of minimizing memory overhead when removing anti and output dependences.

### 2.2.1 Defining the transformation

Consider the following loop  $L_3$ :

```

for  $i := 1$  to  $N$  do
  ...
   $S_k: lhs(f(i)) = rhs(\dots)$ 
  ...

```

and assume we want to remove some anti and output dependences due to the access to the array  $lhs^2$  in statement  $S_k$  (say because there are cycles due to such dependences in the dependence graph). What would be the effect on the dependence graph of a transformation like:

```

for  $i := 1$  to  $N$  do
  ...
   $S'_k: temp(f(i)) = rhs(\dots)$ 
   $S_k: lhs(f(i)) = temp(f(i))$ 
  ...

```

Note that we simply evaluate the right hand side into a new temporary array  $temp$  which we copy back to  $lhs$ . Of course, any access to an array element  $lhs(g(i))$  that depends upon the value calculated in statement  $S'_k$  should be replaced by  $temp(g(i))$ . Thus we need to know what are the statement instances which depend upon the value calculated in statement  $S'_k$ , and we have to rely on a powerful dependence analyzer such as Tiny [13], Petit [9], Partita [10], PAF [12] or PIPS [11] (to quote but a few).

Before going further, we point out that the loop nest can be multidimensional. Our discussion is presented for a single loop, but all results extend to several nested loops. The loop nest need not be perfect or uniform or whatever, what really matters is the availability of a good dependence analyzer capable of providing sources and sinks of all dependences. We do have a restriction, however: to perform our transformation we must assume that the access function  $f$  to the left-hand side array  $lhs$  is injective. The reason for this is explained below in Section 2.2.2, when discussing self output dependences. Note that the two transformations of Padua and Wolfe have the same requirement.

---

<sup>2</sup> $lhs$  and  $rhs$  stand for left-hand side and right-hand side respectively.

Figure 5: A statement  $S$  with in-coming and out-going dependences a) before and b) after transformation.

### 2.2.2 Applying the transformation

Consider statement  $S_k$  in loop  $L_3$ . There can be flow, anti and output dependences going to or coming from  $S_k$ , hence six kinds of arrows in the dependence graph (see Figure 5<sup>3</sup>). We discuss hereafter the impact of our transformation on each of these arrows. Of course there is a new flow dependence  $f_{new}$  from  $S'_k$  to  $S_k$ . Note also that there is no self output loop on  $S'_k$  because we have supposed that the access functions to the left-hand side arrays are injective.

- **In-coming flow dependence** (Figure 6). One of the data read in the right-hand side of statement  $S_k$  was previously produced in the left-hand side of a statement  $S_l$ . After the transformation, the data is read in the right-hand side of statement  $S'_k$ . Thus there is a flow dependence from  $S_l$  to  $S'_k$ .

Figure 6: In-coming flow dependence a) before and b) after transformation.

- **In-coming anti dependence** (Figure 7). A statement  $S_l$  reads  $lhs(f(i))$  before  $S_k$  writes it. After the transformation,  $lhs(f(i))$  is still read by  $S_l$  and is still written by  $S_k$ . Thus, the anti-dependence from  $S_l$  to  $S_k$  is left unchanged.
- **In-coming output dependence** (Figure 8). A statement  $S_l$  writes  $lhs(f(i))$  before  $S_k$  writes it. After the transformation  $lhs(f(i))$  is still written by  $S_l$  and by  $S_k$ . So, there is an output dependence from  $S_l$  to  $S_k$ .

<sup>3</sup>In the figure  $f_{in}$  stands for an in-coming flow dependence,  $f_{out}$  stands for an out-going flow dependence, and so on.

Figure 7: In-coming anti dependence a) before and b) after transformation.

Figure 8: In-coming output dependence a) before and b) after transformation.

- **Out-going flow dependence** (Figure 9). A statement  $S_l$  reads the value of  $lhs(f(i))$  produced by  $S_k$ . Thus the access to  $lhs$  in  $S_l$ , denoted  $lhs(g(i))$ , was replaced by an access to  $temp$ , denoted  $temp(g(i))$ . Now, as  $temp(f(i))$  is written by  $S'_k$ , there is a flow dependence from  $S'_k$  to  $S_l$ .

Figure 9: Out-going flow dependence a) before and b) after transformation.

- **Out-going anti dependence** (Figure 10). One of the data read in the right-hand side of statement  $S_k$  is written afterwards in a statement  $S_l$ . After the transformation this data is read in the right-hand side of statement  $S'_k$ . Thus there is an anti dependence from  $S'_k$  to  $S_l$ .
- **Out-going output dependence** (Figure 11). A statement  $S_l$  writes  $lhs(f(i))$  after  $S_k$  writes it. After the transformation,  $lhs(f(i))$  is still written by  $S_l$  and by  $S_k$ . Thus, there is an output dependence from  $S_k$  to  $S_l$ .

Figure 10: Out-going anti dependence a) before and b) after transformation.

Figure 11: Out-going output dependence a) before and b) after transformation.

All these results are summarized in Figure 5. Note that self loops are processed as the other edges: the less obvious case is a self anti-dependence loop on statement  $S_k$ ; since it comes from  $S_k$  and goes to  $S_k$ , it will be replaced by an anti dependence edge coming from  $S'_k$  and going to  $S_k$ .

Next we show the usefulness of our transformation. If we transform all vertices of a dependence graph, then the only cycles that may remain are pure flow dependence cycles (only made up with edges labeled  $f$ ) or pure output dependence cycles (only made up with edges labeled  $o$ ).

**Theorem 1** *Let  $G$  be the dependence graph of a loop nest  $L$ , and let  $G'$  be the graph obtained from  $G$  by transforming all its nodes. Then a cycle  $C$  of  $G'$  is only composed of flow dependences or is only composed of output dependences. Furthermore,  $C$  corresponds to a cycle that was already a cycle of  $G$ .*

**Proof:** Figure 5 may help follow the proof. Assume that  $G'$  has a cycle  $C$ , and consider an arbitrary edge  $e$  of  $C$ . Then  $e$  corresponds either to a flow, an output or an anti dependence:

- $e$  is an **output dependence** edge. Then, according to Figure 5,  $e$  is an edge from a node  $S_k$  to a node  $S_l$ . As the only edges going out  $S_l$  are output dependences, the edge following  $e$  in  $C$  is an output dependence edge. Thus  $C$  is only composed of output dependence edges. Furthermore, all edges of  $C$  are also edges of  $G$ . Thus  $C$  is also a cycle of  $G$ .
- $e$  is an **anti dependence** edge. Then  $e$  goes from a node  $S'_k$  to a node  $S_l$ . As the only edges coming from  $S_l$  are output dependences, the edge following  $e$  in  $C$  is an output dependence

edge. From the previous case ( $e$  is an output dependence), we conclude that  $C$  is only composed of output dependence edges. This contradicts the hypothesis that  $e$  is an anti dependence edge. Thus  $C$  contains no anti dependence edges.

- $e$  is a **flow dependence** edge. Then either  $e$  is a new flow edge from a node  $S'_k$  to the node  $S_k$ , or  $e$  goes from a node  $S'_k$  to a node  $S'_l$ :
  - $e : S'_k \xrightarrow{f_{\text{new}}} S_k$ . As the only edges coming from a node  $S_k$  are output dependences, the edge following  $e$  in  $C$  is an output dependence edge. From the first case ( $e$  is an output dependence), we conclude that  $C$  is only composed of output dependence edges. This contradicts the hypothesis that  $e$  is a flow dependence edge.
  - $e : S'_k \xrightarrow{f} S'_l$ . There can be flow and anti dependence edges coming from a node  $S'_l$ . However, the edge which follows  $e$  in  $C$  cannot be an anti dependence edge (because of the conclusion of the case “ $e$  is an anti dependence”). Thus the edge which follows  $e$  in  $C$  is a flow dependence edge and  $C$  is only composed of flow dependence edges. Furthermore, a flow dependence edge  $e$  in  $C$  goes from a node  $S'_k$  and to a node  $S'_l$ . Thus there is in  $G$  a flow dependence edge from  $S_k$  to  $S_l$ , and  $C$  corresponds to a cycle that was already a cycle of  $G$ . ■

In other words, pure flow dependence cycles and pure output dependence cycles are not broken when transforming all vertices. But if the original dependence graph contains no such cycles, then the transformed graph is *acyclic*. In fact, from the point of view of breaking cycles, the transformation of a given vertex  $v$  may be useful only if it has an incoming anti or output dependence edge, and an outgoing flow or anti dependence edge (see Figure 5 again). We can summarize this discussion by the following schema:

$$? \xrightarrow{a, \alpha} v \xrightarrow{f, \alpha} ?$$

These are the only paths that are broken by applying our transformation to vertex  $v$ .

Determining the minimum number of vertices to transform (i.e. the minimum number of temporary arrays to use) so that the new dependence graph has only pure flow dependence cycles and pure output dependence cycles turns out to be a difficult problem. In Section 3, we state this problem formally and prove that it is NP-hard. This justifies the introduction of heuristics in Section 4. Beforehand, we work out an example, so as to illustrate our transformation and heuristics.

### 2.3 Target example

Consider the following loop nest  $L_4$ :

```

for  $i := 4$  to  $N$  do
   $S_1: a(i + 5) := c(i - 3) + b(2i + 2)$ 
   $S_2: b(2i) := a(i - 1) + 1$ 
   $S_3: a(i) := c(i + 5) - 1$ 
   $S_4: c(i) := b(2i - 4)$ 

```

The dependence graph is represented in Figure 12. There are six dependences in the loop:

**3 flow dependences** from  $S_3$  to  $S_2$  (because of array  $a$ ), from  $S_2$  to  $S_4$  (because of array  $b$ ), and from  $S_4$  to  $S_1$  (because of array  $c$ ),

Figure 12: The target dependence graph before transformation.

anti	$S_1$	$b(2i + 2)$	$\longrightarrow$	$S_2$	$b(2i)$
flow	$S_1$	$a(i + 5)$	$\longrightarrow$	$S_2$	$a(i - 1)$ [killed]
output	$S_1$	$a(i + 5)$	$\longrightarrow$	$S_3$	$a(i)$
flow	$S_2$	$b(2i)$	$\longrightarrow$	$S_4$	$b(2i - 4)$
anti	$S_3$	$c(i + 5)$	$\longrightarrow$	$S_4$	$c(i)$
flow	$S_3$	$a(i)$	$\longrightarrow$	$S_2$	$a(i - 1)$
flow	$S_4$	$c(i)$	$\longrightarrow$	$S_1$	$c(i - 3)$

Table 1: The dependences found by Tiny.

2 **anti dependences** from  $S_1$  to  $S_2$  (because of array  $b$ ) and from  $S_3$  to  $S_4$  (because of array  $c$ ),  
 1 **output dependence** from  $S_1$  to  $S_3$  (because of array  $a$ ).

Note that Tiny [13] does find the six dependences listed above (see Table 1). In fact Tiny finds a seventh dependence (the second one in Table 1), but recognizes that this dependence is killed. Indeed, we might have found a flow dependence from  $S_1$  to  $S_2$  because  $a(i + 5)$  is written in  $S_1(i)$  (the  $i$ -th instance of  $S_1$ ) and used in  $S_2(i + 6)$ . But meanwhile,  $a(i + 5)$  is re-written in  $S_3(i + 5)$ , and it is this new value which is used in  $S_2(i + 6)$ , hence the source of the dependence for using  $a(i + 5)$  in  $S_2(i)$  is  $S_3(i + 5)$  rather than  $S_1(i)$ . In other words, this flow dependence is overlapped by the succession of the output dependence from  $S_1$  to  $S_3$  and of the flow dependence from  $S_3$  to  $S_2$ . It turns out, in our example, that it is of tremendous importance to have an accurate dependence analyzer capable of detecting that this seven-th dependence is a false one. Otherwise we would have considered that there is a pure flow dependence cycle in the dependence graph !

Consider the effect of transforming vertices  $S_2$  and  $S_3$  in the dependence graph. The new graph  $G'$  is represented in Figure 13.

To illustrate the impact of transforming vertices  $S_2$  and  $S_3$ , we can rewrite the loop using the two temporary arrays **a-temp** (introduced to transform  $S_3$ ) and **b-temp** (introduced to transform  $S_2$ ):

Figure 13: The target dependence graph after transforming  $S_2$  and  $S_3$ .

```

for  $i := 4$  to  $N$  do
   $S_1: a(i + 5) := c(i - 3) + b(2i + 2)$ 
   $S'_2: \mathbf{b-temp}(2i) := \begin{cases} \text{if } i \geq 5 \text{ then } \mathbf{a-temp}(i - 1) + 1 \\ \text{else } a(i - 1) + 1 \end{cases}$ 
   $S_2: b(2i) := \mathbf{b-temp}(2i)$ 
   $S'_3: \mathbf{a-temp}(i) := c(i + 5) - 1$ 
   $S_3: a(i) := \mathbf{a-temp}(i)$ 
   $S_4: c(i) := \begin{cases} \text{if } i \geq 6 \text{ then } \mathbf{b-temp}(2i - 4) \\ \text{else } b(2i - 4) \end{cases}$ 

```

Note that conditional statements are required to process dependences coming from several sources.

### 3 NP-completeness

In this section we prove that the problem of determining the minimal number of statements to split with our transformation is NP-hard. First, we formally state the problem and then we prove that the associated decision problem is NP-complete by reduction from the 3-SAT satisfiability problem. This theoretical result states the complexity of the problem and motivates the search for efficient heuristics (see Section 4). We point out that in the proof we use loop nests with anti dependences only. Even with this simple assumption, the problem still exhibits hard complexity.

#### 3.1 Problem statement

Let  $G = (V, E, \ell)$  be the dependence graph of a loop nest  $L$ . Vertices represent statements. Edges represent dependences between statements. The label of an edge is given by the function  $\ell : E \rightarrow \{f, a, o\}$  (flow, anti or output dependence). Our problem is to determine the minimum number of statements which we should transform using the transformation of Figure 5 so that there remains only pure flow dependence cycles and pure output dependence cycles. The associated decision problem can be stated as follows:

**Definition 1** *Given a loop nest  $L$  (and its dependence graph  $G = (V, E, \ell)$ ) and a nonnegative integer bound  $K$ , can we find no more than  $K$  vertices of  $G$  such that transforming these vertices leads*

to a graph  $G'$  where there remains only pure flow dependence cycles and pure output dependence cycles? (if the answer is yes, we say that  $L \in \text{PURE-CYCL}(K)$ ).

The loop nest  $L$  is said to be admissible if  $G$  only contains anti dependence edges, i.e. edges labeled  $a$ :

**Definition 2** A loop nest  $N$  is admissible iff its dependence graph  $G = (V, E, \ell)$  satisfies to:

$$\forall e \in E, \ell(e) = a.$$

For admissible loop nests, the decision problem can be stated as follows:

**Definition 3** Given an admissible loop nest  $L$  (and its dependence graph  $G = (V, E, \ell)$  where  $\forall e \in E, \ell(e) = a$ ) and a nonnegative integer bound  $K$ , can we find no more than  $K$  vertices of  $G$  such that transforming these vertices leads to an acyclic graph  $G'$  (if the answer is yes, we say that  $L \in \text{NO-CYCL}(K)$ ).

We will prove that  $\text{NO-CYCL}$  is NP-complete in the strong sense, and therefore that  $\text{PURE-CYCL}$  is NP-complete in the strong sense. We use a reduction from a graph-theoretic problem that formalizes our transformation:

**Definition 4** Let  $G = (V, E)$  be a directed graph. Transforming  $s \in V$  amounts to create a new graph  $G' = (V', E')$  such that

1.  $G'$  has a new vertex  $s'$ :  $V' = V \cup \{s'\}$
2.  $E'$  has a new edge  $e = (s', s)$
3. let  $e = (u, v) \in E$ :
  - (a) if  $u \neq s$  then  $e \in E'$
  - (b) if  $u = s$ ,  $e$  is replaced by an edge  $e' = (s', v) \in E'$

Note that the transformation of several vertices of a graph can be performed in any order. We state the following decision graph-theoretic problem:

**Definition 5** Given a graph  $G = (V, E)$  and a nonnegative integer bound  $K$ , can we find no more than  $K$  vertices of  $G$  such that transforming these vertices leads to an acyclic graph  $G'$  (if the answer is yes, we say that  $L \in \text{GRAPH-CYCL}(K)$ ).

We first prove that  $\text{GRAPH-CYCL}$  is NP-complete, by using a reduction from the satisfiability problem  $3\text{SAT}$ . Then we show that  $\text{NO-CYCL}$  is NP-complete.

**Theorem 2**  $\text{GRAPH-CYCL}$  is NP-complete (in the strong sense).

## Proof

First, *GRAPH-CYCL* belongs to NP: given a graph  $G = (V, E)$ , a bound  $K$ , and the list of the vertices to be transformed, we can check in polynomial time whether the new graph  $G'$  is acyclic (this can be done even in linear time  $O(|V| + |E|)$  by traversing it).

We use a reduction from the satisfiability problem *3SAT*. An instance of the *3SAT* problem [5] consists of a boolean expression  $B$  in conjunctive normal form,

$$B = \bigwedge_{i=1}^t C_i$$

- where  $C_j = \ell_j^1 \vee \ell_j^2 \vee \ell_j^3$ ,  $1 \leq j \leq t$ , is a clause
- where each literal  $\ell_j^k$  is a variable or its negation in the set of variables  $X = \{x_1, \dots, x_r\}$

The associated decision problem is represented as follows: does there exist a value assignment  $w : X \rightarrow \{true, false\}$  such that  $B$  evaluates to *true* under  $w$ ? (we say  $B \in 3SAT$ ).

Here is an example that we shall use throughout the proof:  $t = 3$ ,  $r = 4$ , and

$$B = (x_1 \vee \neg x_2 \vee x_4) \wedge (\neg x_1 \vee x_3 \vee \neg x_4) \wedge (x_2 \vee \neg x_3 \vee \neg x_4).$$

Given  $B$ , we have to construct an instance  $g(B)$  of our problem (i.e. a graph  $G = (V, E)$  and a bound  $K$ ) such that  $g(B) \in GRAPH-CYCL(K) \Leftrightarrow B \in 3SAT$ . Furthermore, the construction function  $g$  must be polynomial in the size of  $B$ , i.e. in the number of clauses  $t$  and of variables  $r$ .

**Construction** To help the reader follow the construction, we give intuitive names to the nodes of the graph.

Figure 14: The widget  $W_1$ .

There are  $2 \times t \times r$  vertices in  $G$ . For each variable  $x_i$  we introduce a widget  $W_i$  made of  $2 \times t$  vertices. These vertices are labeled  $T(i, j)$  and  $F(i, j)$ ,  $1 \leq j \leq t$  (see Figure 14). Intuitively, vertex  $T(i, j)$  or  $F(i, j)$  will be used if variable  $x_i$  appears in clause  $C_j$ : we use vertex  $T(i, j)$  if variable  $x_i$  is un-negated in clause  $C_j$ , otherwise we use vertex  $F(i, j)$ . As illustrated in Figure 14, the widget is a complete bipartite graph: there is an edge from any vertex  $T(i, j)$  to every vertex  $F(i, k)$  and vice-versa, with  $1 \leq j, k \leq t$ , which leads to  $2 \times t^2$  edges per widget.

Widgets are connected according to clauses. Consider clause  $C_1$  in the example:  $C_1 = x_1 \vee \neg x_2 \vee x_4$ . We link vertices  $T(1, 1)$ ,  $F(2, 1)$  and  $T(4, 1)$  so as to make a cycle  $T(1, 1) \rightarrow F(2, 1) \rightarrow T(4, 1) \rightarrow T(1, 1)$  in the dependence graph  $G$  (see Figure 15). Similarly, since  $C_2 = \neg x_1 \vee x_3 \vee \neg x_4$ , we link vertices  $F(1, 2)$ ,  $T(3, 2)$  and  $F(4, 2)$  to make another cycle in  $G$ . Therefore, for each clause we add

Figure 15: Connecting widgets from the clauses.

3 edges to  $E$ , leading to a total of  $2 \times r \times t^2 + 3 \times t$  edges in the graph. Clearly, the dependence graph  $G$  does have a size polynomial in  $r$  and  $t$ .

Finally, we let  $K = r \times t$ , hence we ask the question whether it is possible to transform half the vertices so that the resulting graph  $G'$  has no cycle.

**Equivalence** Now we prove that  $g(B) \in \text{GRAPH-CYCL}(K) \Leftrightarrow B \in 3\text{SAT}$ . Assume first that  $B \in 3\text{SAT}$ , and let  $w : X \rightarrow \{\text{true}, \text{false}\}$  be a value assignment such that  $B$  evaluates to *true* under  $w$ . If variable  $x_i$  is assigned to *true* (i.e.  $w(x_i) = \text{true}$ ), then in the widget  $W_i$  we transform the  $t$  vertices  $T(i, j), 1 \leq j \leq t$ , otherwise we transform the  $t$  vertices  $F(i, j), 1 \leq j \leq t$ . Therefore we do transform  $K = r \times t$  vertices in total.

Transforming all the  $T(i, *)$  vertices or all the  $F(i, *)$  vertices ensures that there does not remain any cycle internal to the widget  $W_i$ . Indeed, since the widget is bipartite, all internal cycles go at least through a  $T$  and through a  $F$  node, and one of them is transformed, thereby breaking the cycle.

There remains to prove that the cycles due to the connection of the widgets are broken too. Since  $B \in 3\text{SAT}$ , each clause  $C_j$  evaluates to *true* under the assignment  $w$ . Hence there is at least one variable  $x_i$  in  $C_j$  whose assignment  $w(x_i)$  raises  $C_j$  to *true*. If  $x_i$  appears un-negated in  $C_j$  then  $w(x_i) = \text{true}$  and we transform vertex  $T(i, j)$ . By construction, the cycle due to clause  $C_j$  goes through vertex  $T(i, j)$  and therefore is broken. The reasoning is similar with  $F(i, j)$  if  $x_i$  appears negated in  $C_j$ . Hence there remains no cycle in  $G'$ , and  $g(B) \in \text{GRAPH-CYCL}(K)$ .

Conversely, let  $g(B) \in \text{GRAPH-CYCL}(K)$ , i.e. assume that it is possible to transform at most  $K = r \times t$  vertices so that the resulting graph  $G'$  has no cycle. We have to build a value assignment  $w$  such that  $B$  evaluates to *true* under  $w$ .

Consider a widget  $W_i$ . Since there does not remain any cycle in  $G'$ , at least all the vertices  $T(i, j), 1 \leq j \leq t$ , or all the vertices  $F(i, j), 1 \leq j \leq t$ , must have been transformed. Otherwise, there would remain a vertex  $T(i, j_0)$  and a vertex  $F(i, j_1)$  that have not been transformed, and the cycle of length 2  $T(i, j_0) \rightarrow F(i, j_1) \rightarrow T(i, j_0)$  would not have been broken. Since at most  $K = r \times t$  vertices are transformed in total, and since at least  $t$  vertices per widget are transformed, then exactly  $t$  vertices are transformed per widget, either all the  $T(i, *)$  or all the  $F(i, *)$ .

According to the above discussion, there are exactly  $t$  vertices transformed in widget  $W_i$ , namely either the  $t$  vertices  $T(i, j), 1 \leq j \leq t$  or the  $t$  vertices  $F(i, j), 1 \leq j \leq t$ . We derive a truth assignment function  $w$  by letting  $w(x_i) = \text{true}$  if the transformed vertices are the  $T(i, *)$  and  $w(x_i) = \text{false}$  if the transformed vertices are the  $F(i, *)$ . We have to show that  $w$  is a value assignment such that  $B$  evaluates to *true* under  $w$ . Consider a clause  $C_j, 1 \leq j \leq t$ . The cycle of  $G$  linking the three  $j$ -th nodes of the widgets  $W_i$  such that variable  $x_i$  appears in  $C_j$  has been broken. Hence at least one of these nodes has been transformed, say the one corresponding to variable  $x_{i_0}$ . This transformed node can be either  $T(i_0, j)$  or  $F(i_0, j)$ , depending upon whether  $x_{i_0}$  appears un-negated or negated in  $C_j$ . But if we have transformed  $T(i_0, j)$  then  $w(x_i) = \text{true}$ , and if we have transformed  $F(i_0, j)$  then

$w(x_i) = \text{false}$ . Therefore  $C_j$  evaluates to *true* under  $w$ , and so does  $B$ . Consequently,  $B \in 3SAT$ , and the proof is complete. ■

**Theorem 3** *NO-CYCL is NP-complete (in the strong sense).*

**Proof**

First, *NO-CYCL* belongs to NP: consider an admissible loop nest  $L$  and its dependence graph  $G = (V, E)$ . If the vertices to be transformed are given, we can check in polynomial time whether the new graph  $G'$  is acyclic (this can be done even in linear time  $O(|V| + |E|)$  by traversing it).

We use a reduction from *GRAPH-CYCL*. Given a graph  $G = (V, E)$ , we construct an admissible loop nest  $L$  whose dependence graph is  $G$ .

So let  $G = (V, E)$  be given. All edges in  $G$  must correspond to anti dependences in the loop nest  $L$ . To each vertex  $v \in V$  we associate a linear array  $tab.v$  of size 100 (say). We build the loop nest  $L$  as a single loop surrounding  $|V|$  statements. There is one statement  $S_v$  per vertex  $v$ , whose left hand side is simply  $tab.v(i) = \dots$ . For each edge  $e = (u, v) \in E$  we obtain an anti dependence from  $S_u$  to  $S_v$  by inserting a reference to  $tab.v(i + 1)$  in the right hand side of  $S_u$  as follows:

```

for  $i := 1$  to 99 do
  Statement  $S_u$ :  $tab.u(i) = \dots + tab.v(i + 1) + \dots$ 
  ...
  Statement  $S_v$ :  $tab.v(i) = \dots + \dots$ 

```

The loop nest  $L$  is clearly admissible, as there are neither flow nor output dependences in its dependence graph  $G$ . This construction is clearly polynomial in the size of  $G$ , and the result follows immediately. ■

**Corollary 1** *PURE-CYCL is NP-complete (in the strong sense).*

## 4 Heuristics

In this Section we briefly sketch some heuristics to find out which vertices of the dependence graph  $G = (V, E)$  of a loop nest should be transformed so that there remains only pure cycles in  $G'$ . We give two heuristics, both quite natural. The first one might be very expensive in the worst case, but could be of interest for small dependence graphs. The second one always requires a polynomial time. It runs in time  $O(t^2(|V| + |E|))$ , where  $t$  is the number of transformed vertices, hence a worst case bound  $O(|V|^2(|V| + |E|))$ .

### 4.1 A heuristic based on the hypergraph of the cycles of $G$

May be, the most natural heuristic is to build the hypergraph  $H = (V, F)$  of the cycles of  $G$ .  $F$  is defined as a collection of subsets  $f \subset V$ , where each  $f$  is the set of the vertices of an elementary cycle  $C$  of  $G$ . See Figure 16 for the hypergraph  $H$  of our target example. Furthermore each vertex  $v$  in  $f$  is marked *breakable* if  $C$  is broken when  $v$  is transformed, i.e.  $v$  is marked *breakable* if the in-coming edge of  $v$  in  $C$  is an anti or output dependence, and the out-coming edge a flow or anti dependence.

Figure 16: Hypergraph of the target example. The three elementary cycles are shown with different arrow formats.

Once  $H$  is built, we apply a greedy strategy and transform the vertex  $v_0$  which belongs to, and is *breakable* for, the maximal number of subsets  $f \in F$ . We delete all cycles that were going through  $v_0$  and for which  $v_0$  was breakable. We redo the operation until there remains no cycle in the graph with *breakable* vertices<sup>4</sup>.

The drawback of this heuristic is its high cost in the worst case. Although this is unlikely to happen, the number of cycles can be exponential in the size  $O(|V| + |E|)$  of the graph, and the construction of  $H$  might therefore have a prohibitive cost.

### The heuristic applied to the target example

We show here the transformation of the target example of Section 2.3 using this heuristic. Figure 17 shows the hypergraph corresponding to the dependence graph of Figure 12. The table below (Figure 18) shows for each vertex how many elementary cycles include it as a *breakable* vertex.

Figure 17: Hypergraph of the target example a) before transformation and b) after transformation of node  $S_3$ .

$S_1$	$S_2$	$S_3$	$S_4$
0	1	2	1

Figure 18: Number of circuits which include a vertex as *breakable*.

<sup>4</sup>Here is a small improvement: search whether there exists a subset  $f \in F$  which contains a single *breakable* vertex  $v$ ; if such a vertex exists then transform it (because we have to break it later on anyway to delete the cycle); else search a vertex which belongs to and is *breakable* for the maximal number of subsets  $f \in F$ .

According to this table, the heuristic first transforms node  $S_3$ . The hypergraph of the new graph is shown in Figure 17. As the hypergraph still contains *breakable* nodes, and as  $S_2$  is the only *breakable* node, the heuristic transform  $S_2$  and stops. We obtain the same result as in Section 2.3 (see Figure 13).

## 4.2 A polynomial-time heuristic

Transforming a vertex may be useful only if the corresponding statement has an incoming anti or output dependence, and an outgoing flow or anti dependence. For each vertex  $v$  of the dependence graph we can count its “utility”, i.e. the number  $Util(v)$  of pairs  $(e_{in}, e_{out})$  such that

1.  $e_{in} \in E, e_{in} : ? \rightarrow v$  and  $\ell(e_{in}) \in \{a, o\}$
2.  $e_{out} \in E, e_{out} : v \rightarrow ?$  and  $\ell(e_{out}) \in \{f, a\}$

We transform one of the vertices  $v$  such that  $Util(v)$  is maximal. We obtain a graph  $G'$ . Remove from  $G'$  all the edges which are not in a strongly connected component. If there is at least an anti dependence edge in  $G'$  or if  $G'$  includes an elementary circuit which contains both an output dependence edge and a flow dependence edge, we apply recursively the heuristic on  $G'$ .

The strongly connected components of  $G'$  can be built in  $O(|V| + |E|)$ . To check the presence of an elementary circuit which contains an output dependence edge and a flow dependence edge, we consider a vertex  $v$  with an incoming output dependence and an outgoing flow dependence. If there is a path from a vertex reached by an outgoing flow dependence of  $v$  to a vertex from which starts an incoming output dependence of  $v$ , and if this path does not include  $v$ , then  $G'$  contains at least one non pure circuit. One can check the existence of such a path in one “smart” graph traversal, and thus in time  $O(|V| + |E|)$ . As there are  $|V|$  nodes, the total complexity of this circuit checking is  $O(|V|(|V| + |E|))$ .

In the worst case, all nodes will be transformed and the heuristic complexity is  $O(|V|^2(|V| + |E|))$ .

### The polynomial-time heuristic on the target example

We show here the processing of the target example of Section 2.3 by the polynomial heuristic. The table below shows the value of  $Util$  for each of the graph vertices.

	$S_1$	$S_2$	$S_3$	$S_4$
$Util(v)$	0	1	2	1

Once again,  $S_3$  is transformed first. The new graph has one strongly connected component with an anti dependence (from  $S_1$  to  $S_2$ ): the heuristic is applied once again. The new value of  $Util$  is then:

	$S_1$	$S_2$	$S_4$
$Util(v)$	0	1	0

Thus the polynomial-time heuristic transforms  $S_2$ . We retrieve the same result as before.

## 5 Conclusion

In this paper we have formalized Padua and Wolfe’s transformation [8], to eliminate anti and output dependences. We have stated a complexity result that shows the difficulty of the problem, even in the restricted framework that we have considered.

Note that we have dealt with transformations which increase memory requirements only by a factor proportional to the number of statements. In the general case we also aim at suppressing output dependence cycles, which may require array expansions, thus changing the order of magnitude for the memory requirements: e.g. for a single loop with  $k$  statements, we might go from  $O(k \times N)$  memory units to  $O(k \times N^2)$ . Further work will be devoted to the systematic study of such transformations.
