Abstract— We are presenting new and efficient methods for numerical differentiation, i.e., for estimating derivatives of a noisy time signal. They are illustrated, via convincing numerical simulations, by the analysis of an academic signal and by the feedback control of a nonlinear system.

I. INTRODUCTION

A. Numerical differentiation

Numerical differentiation, i.e., the derivatives estimation of noisy time signals, is an important but difficult ill-posed theoretical problem. It has attracted a lot of attention in many fields of engineering and applied mathematics (see, e.g., in the recent control literature [2], [3], [4], [14], [15], [16], [17], [18], [19], [23], and the references therein). Our purpose here is to improve a new approach which started in [8], [13], and in [7], [9], [10], for solving various questions in control and in signal and image processing. Let us briefly describe our differentiators which are obtained via iterated time integrals of the noisy signal.

B. Short summary of our approach

Start with the first degree polynomial time function $p_1(t) = a_0 + a_1t$, $t \geq 0$, $a_0, a_1 \in \mathbb{R}$. Rewrite thanks to classic operational calculus (cf. [25]) p_1 as $P_1 = \frac{a_0}{s} + \frac{a_1}{s^2}$. Multiply both sides by s^2 :

$$s^2P_1 = a_0s + a_1 \quad (1)$$

Take the derivative of both sides with respect to s , which corresponds in the time domain to the multiplication by $-t$ (cf. [25]):

$$s^2 \frac{dP_1}{ds} + 2sP_1 = a_0 \quad (2)$$

The coefficients a_0, a_1 are obtained via the triangular system of equations (1)-(2). We get rid of the time derivatives, i.e., of sP_1 , s^2P_1 , and $s^2 \frac{dP_1}{ds}$, by multiplying both sides of equations (1)-(2) by s^{-n} , $n \geq 2$. The corresponding iterated time integrals are low pass filters which attenuate the corrupting

noises, which are viewed as highly fluctuating phenomena (see [6] for more details). A quite short time window is sufficient for obtaining accurate values of a_0, a_1 .

The extension to polynomial functions of higher degree is straightforward. For derivatives estimates up to some finite order of a given smooth function $f : [0, +\infty) \rightarrow \mathbb{R}$, take a suitable truncated Taylor expansion around a given time instant t_0 , and apply the previous computations. Utilizing sliding time windows permit to estimate derivatives of various orders at any sampled time instant.

C. Difficulties and improvements

The above method becomes more and more ill-conditioned for higher order truncation of the Taylor expansion. This is a major impediment for obtaining good estimates for higher order derivatives in a noisy setting. Using elimination techniques and Jacobi orthogonal polynomials (see, e.g., [1], [24]), we propose here individual and independent derivatives estimators for each given order. A judicious choice of the point at which the derivatives are estimated in each sliding time window permits to take advantage of the extra-modeling capability afforded by a higher order truncation.

D. Organization of our paper

Section II discusses the mathematical foundations of our differentiators. The first illustration in Section III applies the above techniques for estimating the derivative of a noisy academic signal. The second illustration in Section IV, which is borrowed from [5], deals with the nonlinear feedback control of a DC motor joined to an inverted pendulum through a torsional spring. We provide in both cases convincing computer simulations¹.

¹Interested readers may obtain the corresponding computer programs from one of the authors (cedric.join@cran.uhp-nancy.fr). Reference [11], from which the second example is taken, contains many more applications to various topics in nonlinear control. Most useful discussions and comparisons may be found in [21] where an interesting concrete case-study is analyzed.

II. DERIVATIVES ESTIMATION

Let $y(t) = x(t) + n(t)$ be a noisy observation on a finite time interval of a real-valued signal $x(t)$, the derivatives of which we want to estimate. Assume that $x(t)$ is analytic on this time interval. Consider without any loss of generality the convergent Taylor expansion $x(t) = \sum_{i \geq 0} c_i \frac{t^i}{i!}$ at $t = 0$. The truncated Taylor expansion $x_N(t) = \sum_{i=0}^N c_i \frac{t^i}{i!}$ satisfies the differential equation $\frac{d^{N+1}}{dt^{N+1}} x_N(t) = 0$. It reads in the operational domain as

$$s^{N+1} \hat{x}_N(s) = s^N x_N(0) + s^{N-1} \dot{x}_N(0) \dots + x_N^{(N)}(0) \quad (3)$$

where $\hat{x}_N(s)$ is the operational analog of $x_N(t)$. To ease the notation, we subsequently ignore the argument s .

A. Simultaneous estimation

Replace $x_N(t)$ by the noisy observed signal $y(t)$. Then the estimates $\tilde{x}_N^{(i)}(0)$ of the derivatives at the origin $x_N^{(i)}(0) \triangleq \left. \frac{d^i}{dt^i} x(t) \right|_{t=0}$ are directly obtained from the linear triangular system of equations (see [8], [13])

$$s^{-\nu} \frac{d^m}{ds^m} \left\{ \tilde{x}_N(0) s^N + \dots + \tilde{x}_N^{(N-1)}(0) s + \tilde{x}_N^{(N)}(0) \right\} = s^{-\nu} \frac{d^m}{ds^m} \left\{ s^{N+1} \hat{y} \right\} \quad (4)$$

$m = 0, \dots, N$, where $\nu \geq N + 2$ ensures strict properness. To obtain the numerical estimates, it suffices to express (4) back in the time domain, using the classical rules of operational calculus ([25]). Denote by T the estimation time. We end up with the following closed form expression

$$\mathcal{P}_\nu(T) \begin{bmatrix} \tilde{x}_N(0) \\ \dot{\tilde{x}}_N(0) \\ \vdots \\ \tilde{x}_N^{(N)}(0) \end{bmatrix} = \int_0^T Q_\nu(\tau) y(\tau) d\tau \quad (5)$$

where the nonzero entries of the triangular matrix $\mathcal{P}_\nu(T)$ are given, for $i = 0, \dots, N$, $j = 0, \dots, N - i$, by

$$\{\mathcal{P}_\nu(T)\}_{ij} = \frac{(N-j)!}{(N-i-j)!} \frac{T^{\nu-N+i+j-1}}{(\nu-N+i+j-1)!}$$

and

$$\{Q_\nu(\tau)\}_i = \sum_{\ell=0}^i q_{i,\ell} (T-\tau)^{\nu-N-2-\ell} \tau^{i-\ell}$$

with

$$q_{i,\ell} = \binom{i}{\ell} \frac{(N+1)!}{(N+1-\ell)!} \frac{(-1)^{i-\ell}}{(\nu-N-2-\ell)!}$$

Finally, for each estimation time interval of length T , $I_{t+}^T = [t, t+T]$, we obtain the derivatives estimates at time t by replacing $y(t)$ in (5) by $y(t+\tau)$. These estimates are however not causal. To obtain causal estimates, i.e., the estimates at time t , based on the signal observation in $I_{t-}^T = [t-T, t]$, it suffices to replace $y(t+\tau)$ by $-y(t-\tau)$, $\tau \in [0, T]$.

B. Individual estimation

The matrix $\mathcal{P}_\nu(T)$ in (5) is in general ill-conditioned, and yields therefore poor estimates especially in a noisy setting. A solution to this problem is to obtain an independent estimator for each order of derivation². Reconsider (3). Examine for $0 \leq n \leq N$ the n^{th} order derivative. Annihilate the remaining coefficients $x_N^{(j)}(0)$, $j \neq n$ by multiplying by linear differential operators of the form

$$\Pi_\kappa^{N,n} = \frac{d^{n+\kappa}}{ds^{n+\kappa}} \cdot \frac{1}{s} \cdot \frac{d^{N-n}}{ds^{N-n}} \quad \kappa \geq 0$$

It yields the following estimator for $x^{(n)}(0)$

$$\frac{\tilde{x}_N^{(n)}(0)}{s^{\nu+n+\kappa+1}} = \frac{(-1)^{n+\kappa}}{(n+\kappa)!(N-n)!} \frac{1}{s^\nu} \Pi_\kappa^{N,n} (s^{N+1} \hat{x}) \quad (6)$$

which is strictly proper whenever ν is of the form $\nu = N + 1 + \mu$, $\mu \geq 0$. We obtain a family of strictly proper estimators which is parametrized by κ , μ and N . Write $\tilde{x}_0^{(n)}(\kappa, \mu; N)$ the corresponding estimator. If $N = n$ the differential operator $\Pi_\kappa^{N,n}$ reduces to $\Pi_\kappa^n = \frac{d^{n+\kappa}}{ds^{n+\kappa}} \cdot \frac{1}{s}$: we will then use the simplified notation $\tilde{x}_0^{(n)}(\kappa, \mu)$. The following result is straightforward:

Lemma 1: For any $N \geq n$ and $\mu \geq 0$, $\tilde{x}_0^{(n)}(\kappa, \mu; N)$ in (6) belongs to the set

$$\mathcal{F} = \text{span}_{\mathbb{Q}} \{ \tilde{x}_0^{(n)}(\kappa_\ell, \mu_\ell), \ell = 0, \dots, \min(n+\kappa, N-n) \} \quad (7)$$

where $\kappa_\ell = \kappa + N - n - \ell$ and $\mu_\ell = \mu + \ell$.

Proof: Set $q = N - n$ and $p = n + \kappa$. The proof follows by direct inspection, upon writing $\Pi_\kappa^{N,n} (s^{N+1} \hat{x})$ in the form

$$\begin{aligned} \Pi_\kappa^{N,n} (s^{N+1} \hat{x}) &= \sum_{i=0}^q \binom{q}{i} \frac{(q+1)!}{(q+1-i)!} \frac{d^p}{ds^p} \left\{ s^{q-i} (s^n \hat{x})^{(q-i)} \right\} \\ &= \sum_{i=0}^q \sum_{j=i}^{\min(p, q-i)} a_{i,j} s^{q-j} \Pi_{\kappa+q-j}^n \{ s^{n+1} \hat{x} \} \end{aligned} \quad (8)$$

where

$$a_{i,j} = \binom{q}{i} \binom{p}{j-i} \frac{(q+1)!}{(q+1-i)(q-j)!}$$

This lemma shows that an n^{th} -order truncated Taylor expansion is appropriate for estimating the n^{th} -order derivative. ■

C. Least squares interpretation³

A common way for estimating the derivatives of a signal is to resort to a least squares polynomial fitting on an interval and then take the derivatives of the resulting polynomial function. The estimators derived here rely however on a different approach: the derivatives are estimated pointwise. This departure is furthermore apparent with the developments of the preceding subsection. Nonetheless, a least squares interpretation may be attached to our approach, as shown below.

Start with the estimation of the first order derivative.

²The system (5) being triangular, a closed-form expression for the estimator of $x^{(i)}(t)$ may be derived from it. The corresponding solutions would however exhibit the same sensitivity to noise perturbations.

³The authors would like to thank A. Sedoglavic for bringing this question to their attention.

a) $N = 1$: With $\nu = \mu + 2$, equation (6) becomes

$$\frac{1}{s^{\mu+\kappa+4}} \tilde{x}_0(\kappa, \mu) = \frac{(-1)^{\kappa+1}}{(\kappa+1)!} \left(\frac{\hat{x}^{(\kappa+1)}}{s^{\mu+1}} + (\kappa+1) \frac{\hat{x}^{(\kappa)}}{s^{\mu+2}} \right) \quad (9)$$

It reads in the time domain:

$$\tilde{x}_0(\kappa, \mu) = \frac{\mu+2}{T} \binom{\mu+\kappa+3}{\kappa+1} \int_0^1 p(\tau) \tau^\kappa (1-\tau)^\mu y(T\tau) d\tau \quad (10)$$

where $p(\tau) = (\mu+\kappa+2)\tau - (\kappa+1)$, and T is the estimation time (the estimation interval is I_{0+}^T). We replace of course the signal x by its noisy observation y .

Consider now the Jacobi orthogonal polynomials (cf. [24], [1]) $\{P_i^{\kappa,\mu}(t)\}_{i \geq 0}$, associated to the weight function $w_{\kappa,\mu}(t) = t^{\kappa+1}(1-t)^{\mu+1}$ on the interval $[0, 1]$.

Lemma 2: The first order derivative estimate, given in equation (10), reads as

$$\begin{aligned} \tilde{x}_0(\kappa, \mu) &= \frac{1}{\|P_0^{\kappa,\mu}(t)\|^2} \int_0^1 P_0^{\kappa,\mu}(\tau) w_{\kappa,\mu}(\tau) \dot{y}(T\tau) d\tau \\ &\triangleq \frac{\langle P_0^{\kappa,\mu}(\tau), \dot{y}(T\tau) \rangle_{\kappa,\mu}}{\|P_0^{\kappa,\mu}(\tau)\|^2} \end{aligned} \quad (11)$$

Proof: Observe that $P_0^{\kappa,\mu}(t) = 1$ and $p(\tau)\tau^\kappa(1-\tau)^\mu = -\frac{d}{d\tau}\{\tau^{\kappa+1}(1-\tau)^{\mu+1}\}$. Integration by parts shows that the integral in (10) reduces to $T\langle P_0^{\kappa,\mu}(\tau), \dot{y}(T\tau) \rangle_{\kappa,\mu}$. The equality $\|P_0^{\kappa,\mu}\|^2 = \frac{(\mu+1)!(\kappa+1)!}{(\kappa+\mu+3)!}$ completes the proof. ■

This estimate of the first order derivative appears as the orthogonal projection of the unobserved signal derivatives, on $P_0^{\kappa,\mu}(t)$. Expanding $\dot{x}(T\tau)$, $\tau \in [0, 1]$ in the basis of the Jacobi polynomials

$$\dot{x}(T\tau) = a_0 P_0^{\kappa,\mu}(\tau) + a_1 P_1^{\kappa,\mu}(\tau) + a_2 P_2^{\kappa,\mu}(\tau) + \dots \quad (12)$$

shows that $\tilde{x}_0(\kappa, \mu)$, which coincides with a_0 , actually turns out to correspond to an estimate of $\dot{x}(T\tau_0)$ for some $\tau_0 > 0$. Using a first order approximation of $\dot{x}(T\tau)$

$$\dot{x}(T\tau_0) \approx a_0 P_0^{\kappa,\mu}(\tau_0) + a_1 P_1^{\kappa,\mu}(\tau_0) = a_0$$

allows one to identify τ_0 as the solution of $P_1^{\kappa,\mu}(\tau_0) = 0$. This value of τ_0 , given by

$$\tau_0 = \frac{\kappa+2}{\mu+\kappa+4} \quad (13)$$

is ‘‘experimentally’’ confirmed by the numerical simulations below. The resulting derivative estimation is thus subject to a time delay.

b) $N = 2$: It allows to avoid such a delay, which may not be tolerable in real-time processing. Equation (8) yields

$$\begin{aligned} \frac{\tilde{x}_0(\kappa, \mu; 2)}{s^{\mu+\kappa+5}} &= \frac{(-1)^{\kappa+1}}{(\kappa+1)!} \left\{ \left(\frac{\hat{x}^{(\kappa+2)}}{s^{\mu+1}} + (\kappa+2) \frac{\hat{x}^{(\kappa+1)}}{s^{\mu+2}} \right) \right. \\ &\quad \left. + (\kappa+3) \left(\frac{\hat{x}^{(\kappa+1)}}{s^{\mu+2}} + (\kappa+1) \frac{\hat{x}^{(\kappa)}}{s^{\mu+3}} \right) \right\} \end{aligned} \quad (14)$$

It reads in the time domain after some algebraic manipulations:

$$\begin{aligned} \tilde{x}_0(\kappa, \mu; 2) &= \frac{\langle P_0^{\kappa,\mu}(\tau), \dot{y}(T\tau) \rangle_{\kappa,\mu}}{\|P_0^{\kappa,\mu}\|^2} \\ &\quad + P_1^{\kappa,\mu}(0) \frac{\langle P_1^{\kappa,\mu}(\tau), \dot{y}(T\tau) \rangle_{\kappa,\mu}}{\|P_1^{\kappa,\mu}\|^2} \end{aligned} \quad (15)$$

where $P_1^{\kappa,\mu}(0) = -\tau_0 = -\frac{\kappa+2}{\mu+\kappa+4}$. We therefore deduce that $\tilde{x}_0(\kappa, \mu; 2)$ corresponds to an estimate of the first order derivative $\dot{x}(t)$ at $t = 0$. The estimation of $\dot{x}(t)$ from a second order truncation of the Taylor expansion is therefore delay free.

We now show how this interpretation can be exploited to obtain better estimates. According to Lemma 1 and using (14), it is easy to verify that the relation

$$\tilde{x}_0(\kappa, \mu; 2) = \lambda_0 \tilde{x}_0(\kappa, \mu + 1) + \lambda_1 \tilde{x}_0(\kappa + 1, \mu) \quad (16)$$

holds for $\lambda_0 = \kappa + 3$ and $\lambda_1 = -(\kappa + 2)$. Let us now extend the set \mathcal{F} in (7), by allowing the coefficients of the linear combinations therein to be real, rather than rational. In particular, given a point $\tau_1 \in [0, 1]$, one may always choose the λ_i 's such that (16) becomes

$$\begin{aligned} \tilde{x}_{\tau_1}(\kappa, \mu; 2) &= \frac{\langle P_0^{\kappa,\mu}(\tau), \dot{y}(T\tau) \rangle_{\kappa,\mu}}{\|P_0^{\kappa,\mu}\|^2} \\ &\quad + P_1^{\kappa,\mu}(\tau_1) \frac{\langle P_1^{\kappa,\mu}(\tau), \dot{y}(T\tau) \rangle_{\kappa,\mu}}{\|P_1^{\kappa,\mu}\|^2} \end{aligned} \quad (17)$$

In this case, $\tilde{x}_{\tau_1}(\kappa, \mu; 2)$ will represent the estimate of $\dot{x}(T\tau_1)$, obtained from the truncated Taylor expansion $x_2(t) = x(\tau) + \dot{x}(\tau)(t-\tau) + \frac{\ddot{x}(\tau)}{2}(t-\tau)^2 = x_2(0) + [\dot{x}(\tau) - \tau\ddot{x}(\tau)]t + \frac{\ddot{x}(\tau)}{2}t^2$ at $\tau = T\tau_1$. A direct verification will show that the values for λ_0 and λ_1 , associated to τ_1 are given by $\lambda_0 = (\kappa + 3) - (\mu + \kappa + 5)\tau_1$ and $\lambda_1 = 1 - \lambda_0$.

Let us now turn to the question pertaining to the selection of a value for τ_1 . Expansion (12) shows that a good choice for τ_1 is given by the smallest (resp. largest) root of the polynomial $P_2^{\kappa,\mu}$ when the estimation interval is I_{t+}^T (resp. I_{t-}^T). Indeed, choosing τ_1 as a zero of $P_2^{\kappa,\mu}$ annihilates the contribution of the orthogonal projection of the signal on $P_2^{\kappa,\mu}$ in the estimation error. On the other hand, recall that τ_1 (resp. $1 - \tau_1$ for I_{t-}^T) represents a delay in the estimation. Choosing the smallest (resp. largest) root thus translates to a lower delay. Note also that the delay τ_1 is smaller than τ_0 , since the zeros of $P_2^{\kappa,\mu}$ and $P_1^{\kappa,\mu}$ interlace.

The above analysis may be easily generalized to the n^{th} order derivative estimation, $n \geq 2$.

III. FIRST ILLUSTRATION: DERIVATIVE OF A NOISY SIGNAL

Let $y(t) = x(t) + n(t)$, $0 \leq t \leq 5$, be a noisy measurement of the signal

$$x(t) = \tanh(t-1) + e^{-t/1.2} \sin(6t + \pi)$$

The noise level, measured by the signal to noise ratio in dB, i.e., $SNR = 10 \log_{10} \left(\frac{\sum |y(t_i)|^2}{\sum |n(t_i)|^2} \right)$, corresponds to $SNR = 25$ dB (see Figure 1). In all the subsequent numerical simulations, the integrals are computed via the classical trapezoidal rule.

Begin with the first order derivative and $N = 1$. The estimates $\tilde{x}_0(\kappa, \mu)$, obtained from (10) with $\kappa = \mu = 2$, are displayed in Figure 2 (solid line). It corresponds to the estimation results in the successive intervals I_{t+}^T , with $T = 60T_s$ and for $t = iT_s$, $i = 0, \dots, \lfloor \frac{5-T}{T_s} \rfloor$. The exact

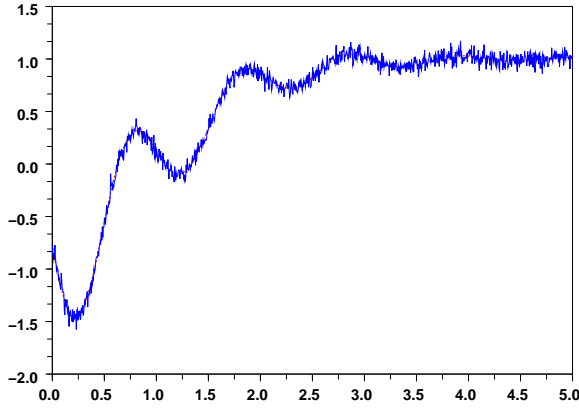

Fig. 1. Noisy observation signal, $SNR = 25dB$.

Fig. 2. Estimation of the signal derivative: $N = 1$.

derivative of the noise-free signal is also displayed (dashed line) in order to gauge the estimation accuracy. For this, we have introduced a shift corresponding to the delay τ_0 in (13). Observe how this predicted value of τ_0 fits with the experiment. Of course with $N = 1$, the truncated Taylor series model is linear, resulting in poor estimates on the intervals where the signal's dynamic is strong. For high signal-to-noise ratio, the estimates may be improved by reducing the estimation time T . Alternatively, one may consider a richer signal model, *e.g.*, with $N = 2$. This is the case of the next experiment. We now consider the sliding windows I_{t-}^T , with $T = 110T_s$. The estimates $\tilde{x}_0(\kappa, \mu; 2)$, based on (14), (15), are plotted (solid line) in Figure 3 below, for $\kappa = \mu = 0$.

There is no estimation delay, as expected. However, the performance significantly degrades as compared to the preceding results although the signal model is more precise. If we now relax this delay-free constraint, it becomes possible to take advantage of the more flexible second order model for the signal.

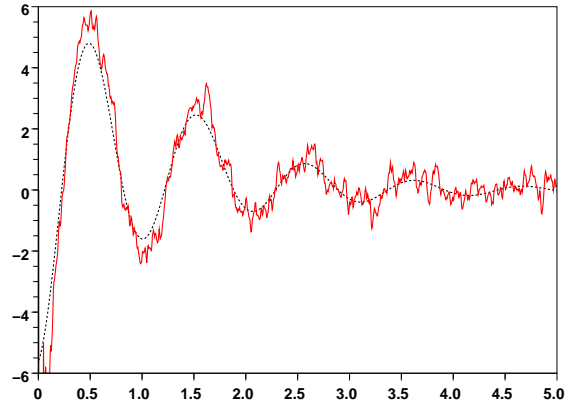

Fig. 3. Estimation of the signal derivative: $N = 2$, no delay

This is illustrated in the following simulation (see Figure 4), where we keep the same settings for T , κ and μ . The solid line curve in Figure 4 represents the estimates obtained

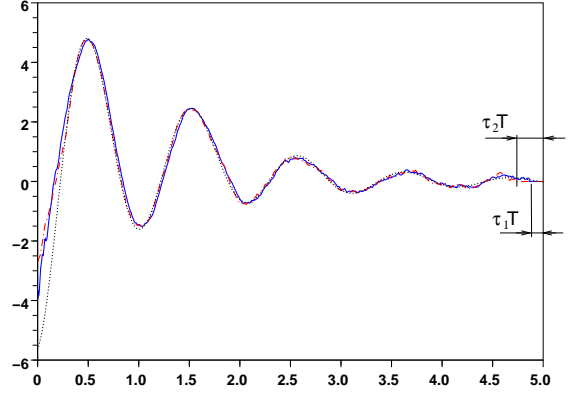

Fig. 4. Estimation of the signal derivative: $N = 2$, with delay τ_1 .

from (16)-(17) where τ_1 is the largest root of $P_2^{\kappa, \mu}$. Using the same idea with $N = 3$, we obtain the estimates $\tilde{x}_0(\kappa, \mu; 3)$, plotted with dashed line. The associated estimator reads as

$$\tilde{x}_0(\kappa, \mu; 3) = \sum_{i=0}^2 \lambda_i \tilde{x}_0(\kappa + 2 - i, \mu + i)$$

where the real coefficients λ_i , $i = 0, 1, 2$ are chosen so that $\tilde{x}_0(\kappa, \mu; 3)$ corresponds to $\dot{x}(\tau_2 T)$, with τ_2 being a root of $P_3^{\kappa, \mu}$. If $\kappa = \mu$, which is the case here, then $\tau_2 = 0.5$ is a common root of all Jacobi polynomials of odd degree. The dashed line curve was obtained with this choice of τ_2 .

IV. SECOND ILLUSTRATION: NONLINEAR FEEDBACK CONTROL

A. System description

Consider with [5] the mechanical system, which consists of a DC-motor joined to an inverted pendulum through a torsional spring:

$$\begin{aligned} J_m \ddot{\theta}_m &= \kappa(\theta_l - \theta_m) - B\dot{\theta}_m + K_\tau u \\ J_l \ddot{\theta}_l &= -\kappa(\theta_l - \theta_m) - mgh \sin(\theta_l) \\ y &= \theta_l \end{aligned}$$

θ_m and θ_l represent respectively the angular deviation of the motor shaft and the angular position of the inverted pendulum. J_m , J_l , h , m , κ , B , K_τ and g are physical parameters which are assumed to be constant and known. This system, which is linearizable by static state feedback, is flat (cf. [12], [22]); $y = \theta_l$ is a flat output, which is measured.

B. Control design

Asymptotic tracking of a given smooth reference trajectory $y^*(t) = \theta_l^*(t)$ is achieved by the feedback controller

$$u = \frac{1}{K_\tau} \left(\frac{J_m}{\kappa} (J_l v + \kappa \dot{y}_e + mgh(\ddot{y}_e \cos y_e - (\dot{y}_e)^2 \sin y_e)) + J_l \ddot{y}_e + mgh \sin y_e \frac{B}{\kappa} (J_l y_e^{(3)} + \kappa \dot{y}_e + mgh \dot{y}_e \cos y_e) \right)$$

where

$$v = [y^*(t)]^{(4)} - \gamma_4 (y_e^{(3)} - [y^*(t)]^{(3)}) - \gamma_3 (\dot{y}_e - \dot{y}^*(t)) - \gamma_2 (\ddot{y}_e - \ddot{y}^*(t)) - \gamma_1 (y_e - y^*(t))$$

The subscript “e” denotes the estimated value. The design parameters $\gamma_1, \dots, \gamma_4$ are chosen so that the resulting characteristic polynomial is Hurwitz. The state θ_m is estimated via

$$[\theta_m]_e = \frac{1}{\kappa} (J_l \dot{y}_e + mgh \sin y_e) + y_e$$

C. Numerical simulations

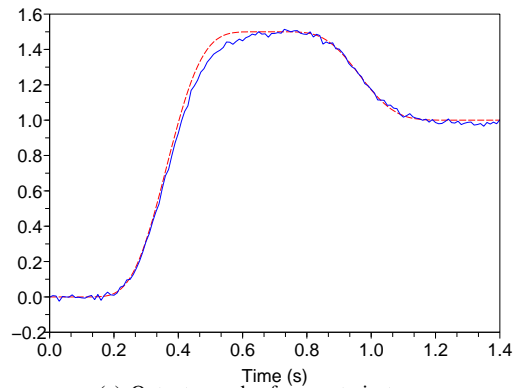

The physical parameters have the same numerical values as in [5]: $J_m = 3.7 \times 10^{-3} \text{ kgm}^2$, $J_l = 9.3 \times 10^{-3} \text{ kgm}^2$, $h = 1.5 \times 10^{-1} \text{ m}$, $m = 0.21 \text{ kg}$, $B = 4.6 \times 10^{-2} \text{ m}$, $K_\tau = 8 \times 10^{-2} \text{ NmV}^{-1}$. The numerical simulations (see also [11]), which are much better than in [13], where less efficient differentiators were employed, are presented in Figures 5. Robustness has been tested with an additive white Gaussian noise $\mathcal{N}(0; 0.01)$ on the output y (this noise level is quite relevant in such applications). Note that the off-line estimations of \dot{y} and θ_m , where a “small” delay is allowed, are more accurate than the on-line estimation of \dot{y} .

V. CONCLUSION

The basic elements of our differentiators are essentially integrators, the advantage of which is twofold: easy implementation and good robustness with respect to noise corruption. Our estimators may be given a least squares interpretation (see [20] for more details), although our approach is based on quite different mathematical ingredients, which are mainly of algebraic flavor. This interpretation is a key point leading to improved numerics.
