Abstract—A *smart surface* is a distributed Micro-Electro-Mechanical System (MEMS) designed for conveying microscopic objects over a meso-scale distance, by the coordinated action of several microcells composed of microsensors, microactuators and control units. We present a high-level description of a smart surface with the System Modeling Language (*SysML*). We show how various SysML views (requirement, block, constraint and parametric diagrams) may accompany the design of such a complex system with precise but simple models. We also establish links between SysML and other technologies and tools for complex system modeling.

Keywords-Smart Surface, SysML, Modeling

I. INTRODUCTION

Current miniaturization and integration trends of electronic devices require to assemble chips and other components that become too small to be directly handled by humans. The future electronics assembly industry will have to scale with the technology, using automated micromachines combining manipulators and intelligent conveying systems.

A *smart surface* is a distributed Micro-Electro-Mechanical System (MEMS) designed to convey microscopic objects over a meso-scale distance. The global conveyance effect results from the coordinated action of microcells spatially organized in a 2D array. Each microcell is composed of a microsensor, a microactuator and a control unit. The control units realize communications with their neighbours and computations to adjust the actuator local effects from the sensor measures.

Modeling such a complex system is a challenge addressed in [1], [2], [3] with the motivation of validating by simulation the realization of a Distributed MEMS Air-flow Surface Micromanipulator (DMASM, see Figure 1). For technological reasons, the corresponding realization was limited to the microactuator layer. Integrating the sensor and control layers was the goal of a multidisciplinary research project named “Smart Surface”, initiated in 2007 and supported by the French Research Agency (ANR).

During this project many attempts have failed to extend the existing models with the distributed control of the microactuators. We claim that the failure is due in some extend to the intrication of the model itself, but also to the modeling language, namely VHDL-AMS [4]. The usual practice of this extension of VHDL to mixed signals was

Figure 1. Conveyance of micro objects

indeed not shared by the physicians, automaticians and computer scientists collaborating in the project. Anticipating this difficulty we have contributed to this project by investigating an adapted language.

A previous work [5] considered a smart surface as a set of heterogeneous *SoC* (System on Chip) systems. System on Chip (*SoC*) refers to integrating all components of an electronic system into a single integrated electronic circuit. It may contain digital, analog, mixed-signal, and often radio-frequency functions all on one chip. A typical application is in the area of embedded systems. The interaction and integration of hardware and software components are essential parts of their design. A preliminary smart surface modeling was realized in [5] with the *UMLASoc* profile.

The present work suggests to use the System Modeling Language (*SysML*) as a better solution for the multidisciplinary modeling of relevant physics (electromechanics, electronics, ...) and control of distributed MEMS. *SysML* is a modeling language for systems engineering. This covers complex systems which include a broad range of heterogeneous domains, in particular hardware and software. Several similarities exist between the methods used in the area of systems engineering and complex *SoC* design, such as the need for accurate requirements capture, system specification and simulation, system validation and verification. There are several works [6], [7], [5] in this area, using *UML* as specification language and checking the properties of

reliability.

This paper addresses the graphical description of a smart surface by *SysML* diagrams. These diagrams help understanding the specification for stakeholders who are not familiar with the *VHDL-AMS* language, such as customers or certification authorities. *SysML* facilitates also communication between project members.

Section II gives a brief description of *SysML*. Section III informally presents the smart surface example. Section IV presents its modeling by various diagrams, including the requirement diagram, two block diagrams and the parametric diagram. Finally, we end up by a conclusion and some perspectives of this work.

II. *SysML*

SysML has been proposed by the Object Management Group (OMG, <http://www.omg.org>) together with the International Council on Systems Engineering (INCOSE, <http://www.incose.org>) and the AP233 consortium (<http://ap233.eurostep.com>) with the aim to define a general purpose modeling language for systems engineering. It is based on the actual standard for software engineering, the Unified Modeling Language (*UML*, <http://www.uml.org>) version 2.0, with some extensions (see figure 2), and it was developed as a response to the request for proposal (RFP) issued by the OMG in March 2003 (http://syseng.omg.org/UML_for_SE_RFP.htm) and adopted as a standard in May 2006 (<http://www.omg-sysml.org>). *SysML* is a modeling language for representing systems and product architectures, as well as their behavior and structure. It adapts to systems engineering standard modeling techniques from software development, and supports the specification, design, analysis, verification and validation of a broad range of complex systems.

Figure 2. Comparison of *SysML* 1.0 with *UML* 2.0

(*SysML*) is the first formal *UML* profile dedicated to the specification of professional engineering systems. It has been developed during many years but has only recently

been fully agreed and standardized. *SysML* has meanwhile evolved over several major iterations, including two separated proposals from different teams. As a consequence of this long and often confusing evolution, there are many misconceptions associated with *SysML*, such as its status as a profile, its autonomy as a language and how it can be applied in a better way for systems engineering. *SysML* significantly extends *UML* with system-related formal constructs, such as real-world physical constraints, physical flows and connections between physical components.

III. Smart Surface INFORMAL DESCRIPTION

A *smart surface* consists of a rectangular grid of rectangular cells. Each cell consists of a microactuator, a microsensor and a microcontroller. The purpose of a smart surface is to sort microscopic objects according to parameters such as their shape and/or colour. The following smart surface characteristics are extracted from a specification document jointly written during the “Smart Surface” project.

A. The grid

- The grid is divided in 24 lines of 24 cells each, a cell having a size of about 2 mm.
- There is no centralized control. Cells communicate step by step through their direct neighbours.

B. Objects to sort

- We assume, at first, that a object should be found from a small number of options (2, 3 or 4).
- Objects to convey are typically included in a square of less than 4 μm a side.

C. Microactuator

- A microactuator can communicate with its 4 neighbours via its cell controller,
- A microactuator acts on the objects through an air-flow (should not be specified at this level).

D. Sorting

- In the first instance, at a given moment, at most one object may be present on the smart surface,
- The sorting will be done according to the shape of the object.

IV. MODELING A SMART SURFACE WITH *SysML*

The former informal specification is obviously incomplete. Even more detailed, it would remain imprecise, due to the ambiguities of natural languages. We suggest to replace it with *SysML* diagrams. Typical instances of the most important diagrams for a smart surface modeling are presented one after the other. Physical concepts and laws are borrowed from [2].

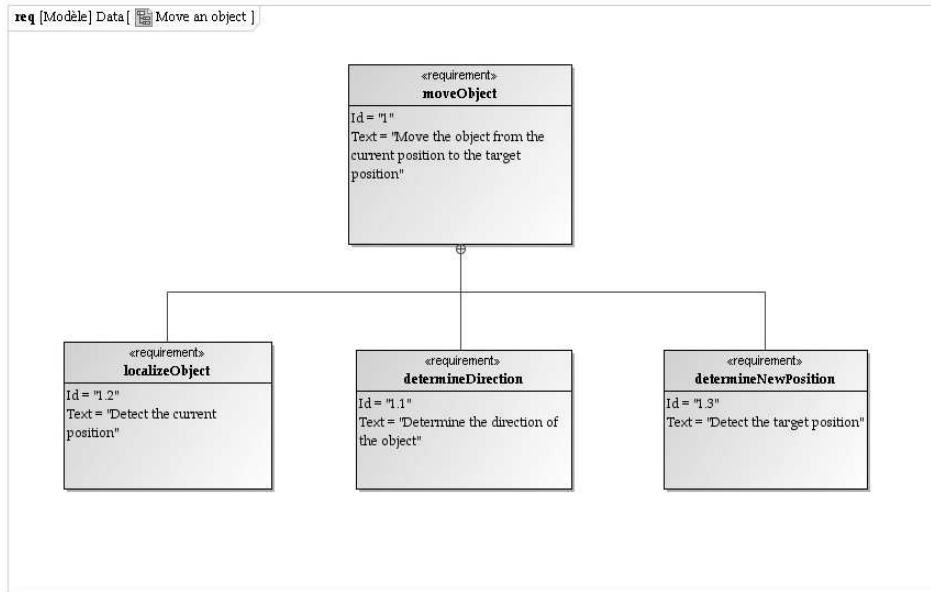

Figure 3. Requirement diagram

A. Requirement diagram

The *SysML* requirement diagram allows several ways to represent requirements relationships. The relationships *derive*, *satisfy*, *verify*, *refine*, *trace* and *hierarchy* are briefly explained below :

- The *derive* relationship relates a derived requirement to its source requirement. In a requirement diagram, the *derive* relationship is represented by the keyword “deriveReq”.
- The *satisfy* requirement describes how a model satisfies one or more requirements. It represents a dependency relationship between a requirement and a model element (from another *SysML* diagram) that fulfills that requirement. This relationship is represented by the keyword “satisfy”. One example is to associate a requirement to a *SysML* block diagram.
- The *verify* relationship defines how a test case can verify a requirement. This includes standard verification methods for inspection, analysis, demonstration or test. The keyword “verify” represents this relationship.
- The *refine* relationship describes how a model element (or set of elements) can be used to later refine a requirement. For example, how a Use Case can represent a requirement in a *SysML* requirement diagram. The relationship is represented in the diagram by the keyword “refine”.
- The *trace* relationship provides a general purpose re-

lationship between a requirement and any other model element. Its semantics has no real constraints and is not well-defined as the other relationships.

- In large and complex systems, it is common to have a hierarchy of requirements, and their organization into various levels helps in dealing with system complexity. *SysML* allows splitting complex requirements into simpler ones, as a hierarchy of requirements related to each other. The advantage is that the complexity of systems is treated from the early beginning of development, by decomposing complex requirements.

In Figure 3, the requirements *localizeObject*, *determineDirection* and *determineNewPosition* are broken down from the requirement *moveObject*.

B. Block Definition Diagram

SysML provides a structural element called a *block*. A block can represent any type of component of the system, physical, logical, functional, or human. Blocks are declared within a *Block Definition Diagram (BDD)* based on the *UML Composite Structure Diagram*, which extends the *UML Class Diagram*. A BDD describes the structure of the system. In particular, it can represent association and composition relationships.

Figure 4 shows an example of a *BDD* with four blocks. It is the first level of modeling of the smart surface, the most abstract. The block named **Smart Surface** represents the system as a whole. It is decomposed into three sub blocks

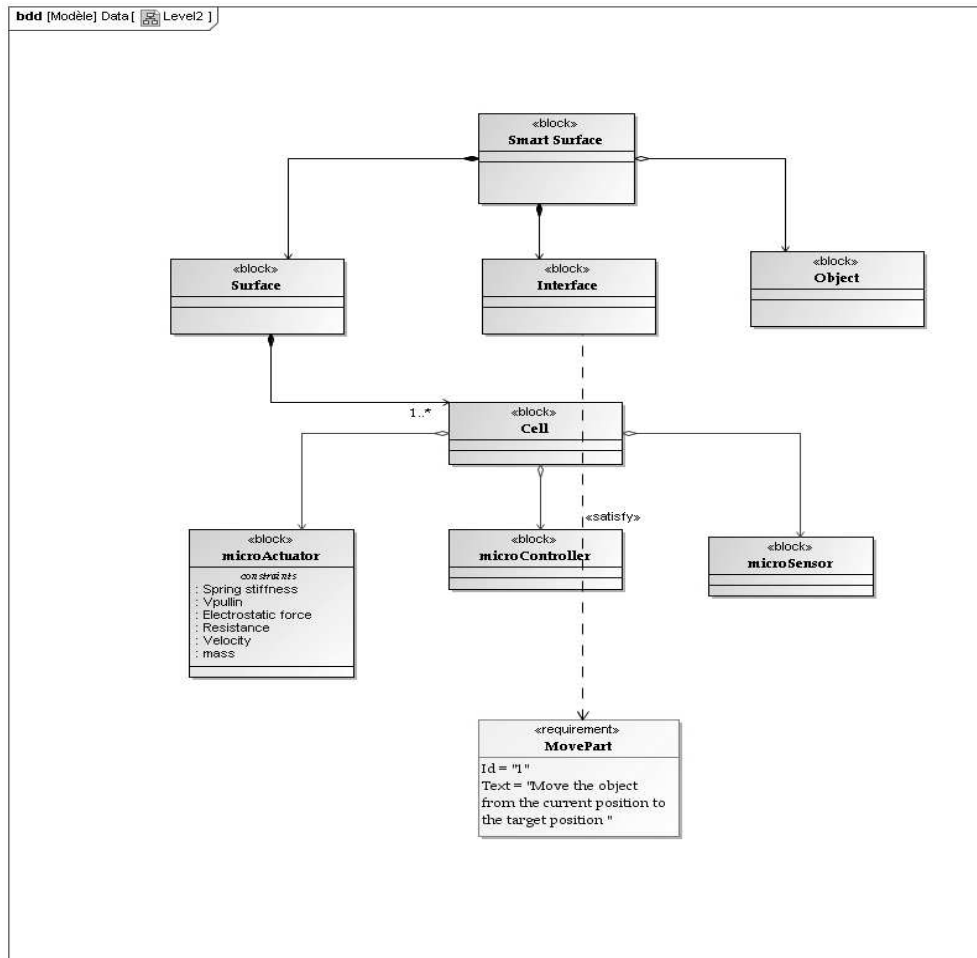

Figure 5. Block Definition Diagram, level 2

(**Surface**, **Interface** and **Object**) and is linked to them by the following relationships :

- composition to the *Surface* and *Interface* blocks,
- aggregation to the *Object* block.

The block named **Object** represents a microscopic object in the *Smart Surface* environment. The block named **Surface** represents the distributed MEMS under design. The block named **Interface** represents all the interactions between **Surface** and **Object**.

At a second (more detailed) level of modeling (see Figure 5), the block **Surface** is linked by composition to a new block named **Cell**. The composition relation with the block **Cell** is labeled with the multiplicity 1..* and expresses that the surface is composed of many cells. The block **Cell** is itself composed of three parts, namely a microactuator, a microsensor and a microcontroller. Each of them is represented by a block.

The two blocks **Surface** and **Cell** represent physical components and together constitute a physical model of the smart surface. On the other hand the block **Interface** is a logical model of the surface interactions with its environment, here reduced to a microscopic object moving above the surface. This concept of interface has been introduced in [2] to model the multiphysical exchanges (mechanical, electrical, fluidic, etc) between a MEMS and its environment.

Requirement traceability is made possible by the definition of a relationship **satisfy** between the **Interface** block and an element of the requirement diagram.

C. Internal Block Diagram

The *Internal Block Diagram (IBD)* allows the designer to refine the structural aspect of the model. The *IBD* is the equivalent in *SysML* of the composite structure diagram in *UML*. In the *IBD*, parts are basic elements assembled to

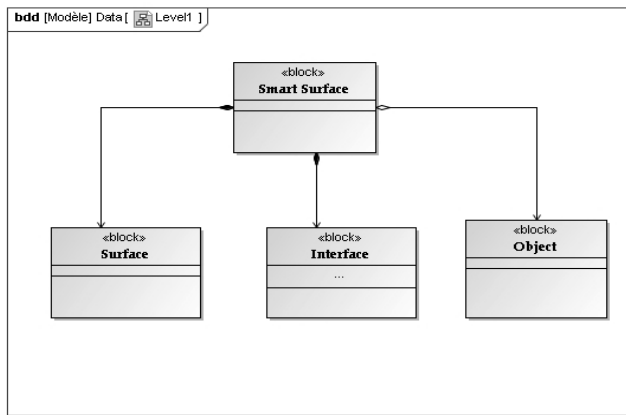

Figure 4. Block Definition Diagram, level 1

define how they collaborate to realize the block structure and/or behavior. In the *IBD* the designer can refine the definition of the interactions between blocks by defining flow ports along the following rules:

- ports are parts available for connection outside of the owning block;
- ports are typed by interfaces or blocks which define what can be exchanged through them;
- ports are connected using connectors which represent the use of an association in the *IBD*.

Two types of ports are available in *SysML*:

- standard ports handling requests and invocations of services with other blocks (basically the same concept as in *UML 2.0*);
- flow ports which let blocks exchange flows of information.

Flow ports specify the interaction points among blocks and parts supporting the integration of behavior and structure. For standard ports, an interface class is used to list the services offered by the block. For flow ports, a flow specification is created to list the type of data that can flow through the port.

Figure 6 shows how to represent the internal structure of the block *Cell* by an *IBD*.

Figure 6 shows two flow ports: the flow port *Direction enable* continuously passes the direction of the object. Through the flow port *Object detection* the microsensor sends to the microcontroller a signal to indicate the detection of an object.

D. Constraint Blocks

A *constraint block* encapsulates a physical property of the system or a constraint on it. Syntactically it is a block labeled with the keyword `<<constraint>>` and identified by a name. The next compartment in the constraint block defines

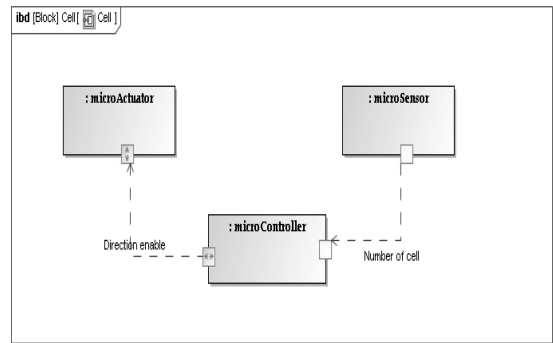

Figure 6. Internal Block Diagram of the *cell* block

the constraint as an arbitrarily complex logical expression, in a formal (e.g. using MathML (<http://www.w3.org/Math>) or OCL (<http://www.omg.org/spec/OCL/2.0>) or informal language. The last constraint block compartment enumerates the constraint parameters as attributes with their type.

Up to here, our smart surface modeling is generic. It does not yet describe the physical structure and behavior of a particular realization. Constraint blocks are the key for this physical description.

As a first example, Figure 7 shows constraint blocks specifying the behavioral laws of a pneumatic microactuator represented in Figure 1 and described in VHDL-AMS in [2]. The constraint block named **Electrostatic force** corresponds to the use case when the microactuator is active and produces an air flow in one direction. Two other constraints not reproduced here correspond to the other two cases, when the microactuator is active in the reverse direction and when it is off.

Constraint blocks define generic constraints that can be reused in multiple contexts. Reusable constraint definitions are specified in block definition diagrams and can be packaged into general-purpose or domain-specific model libraries. For instance the **Velocity** constraint in Figure 7 is a general-purpose definition that could be packaged and imported in the present model.

Along the functional virtual prototyping (FVP) methodology promoted in [1], the constraint blocks presented in Figure 7 take part to a low physical description level called the “component model”. But constraint blocks can also describe the highest global behavioral description level of FVP, called the “behavioral model”. Figure 8 illustrates this with three constraint blocks specifying the interactions between the MEMS array and an object above it. It is a simplified version of the behavioral model described (mathematically and in VHDL-AMS) in [1]. Since it considers the smart surface as a whole, this specification is clearly at the most global modeling level and is a possible realization of the

Figure 7. Constraint blocks of a pneumatic microactuator

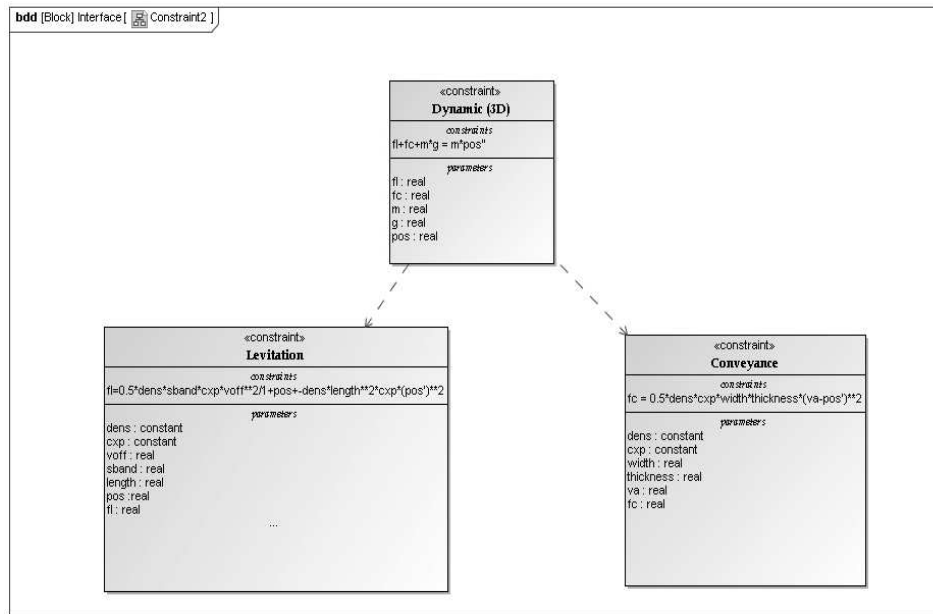

Figure 8. Constraint blocks of the interface

Interface block, as mentioned in the BDD title.

The formulas in the constraint blocks **Horizontal dy-**

Horizontal dynamic and **Vertical dynamic** are two instances of the fundamental law of solid mechanics, respectively expressed along an horizontal axis and the vertical z -axis. The horizontal axis can be assumed to be the x -axis, a similar law not reproduced here also holds along the y -axis. **fl** and **fc** respectively are the levitation and conveyance forces produced by the air-flow, **m** is the object mass and **(posx, posy, posz)** is its position in a 3D Cartesian coordinate system. The **Levitation** and **Conveyance** constraint blocks define approximative laws to compute the intensity of the levitation and conveyance forces, respectively. The conveyed object is assumed to be parallelepipedic with a square side of length **length** and a thickness given by the **thickness** quantity. **dens** is the air density, **exp** is the air pressure, **voff** (resp. **va**) is the air-flow velocity when the microactuator is off (resp. on).

Constraint blocks are linked by a dependency relationship expressing that changes in one model element (the supplier) impact another model element (the client). A dependency relationship can also represent precedence. For example the equation in the block **Conveyance** must be solved before that in the block **Horizontal dynamic**, hence the dependency relationship in Figure 8 between the two blocks.

E. Parametric Diagram

A *Parametric Diagram (PD)* is associated to a block and makes use of constraint blocks, defined in a Block Definition Diagram, as constrain properties for its owning block. It is a new diagram type specific to *SysML*. Syntactically a *PD* is similar to an *IBD*, with the restriction that connectors are either between two constraint parameters or between a constraint parameter and a parameter of the owning block.

Figure 9 shows the PD of the block **Interface**, with connectors between the four constraint blocks from Figure 8. The parameters on the diagram edges are the concrete **Interface** block attributes. Except the gravitational constant **g** the interface attributes either come from the surface (**voff**, **va**) or from the conveyed object (mass **m**, shape characterized by **length** and **thickness**, position defined by **posx** and **posz**).

Figure 10 is the PD of the **microActuator** block. Among others it shows how the mathematical formula which expresses the contact voltage ($V_{pull-in}$) is related to other constraints and quantities. This constraint requires five input parameters. **lv** is the length of vertical suspending beam, **keq** is the spring stiffness, **epsilon** is the dielectric constant of vacuum, **h** is the thickness of suspending beam, and **g0** is the initial gap between electrodes. These values may either come from the external environment or from results of other equations. The **Vpullin** block also provides the output parameter **vpullin**.

V. CONCLUSION AND PERSPECTIVES

We have presented a hierarchical modeling of a smart surface with *SysML*. The first two levels are generic in the

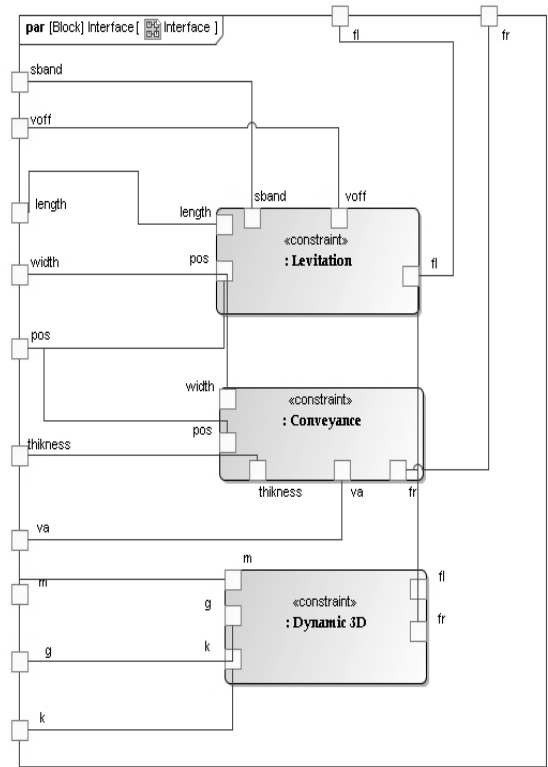

Figure 9. Parametric diagram of the interface block

sense that they can be refined into any physical model of intelligent conveying surface. As an example of possible refinement we have presented *SysML* diagrams corresponding to the distributed MEMS air-flow surface micromanipulator from [1].

As *SysML* is a language, not a methodology, it can be smoothly integrated in any existing design methodology and can thus significantly improve the development process of an organization. There is no need to do radical changes in the current methodology, which would involve too many risks. In addition *SysML* is a *UML*-based language, which is widely known and used, both in academia and industry. It can also facilitate communication between all professionals involved in a system design.

System modeling and simulation traditionally have been performed using quite different tools, e.g., relatively informal graphical diagrams for system description, and formal languages for simulation. The emergence of *SysML* may provide a way to create formal system models, and link them directly to formal simulation languages as *Rosetta* [8]. The potential for this approach is quite interesting, as it would permit users to develop system models that could

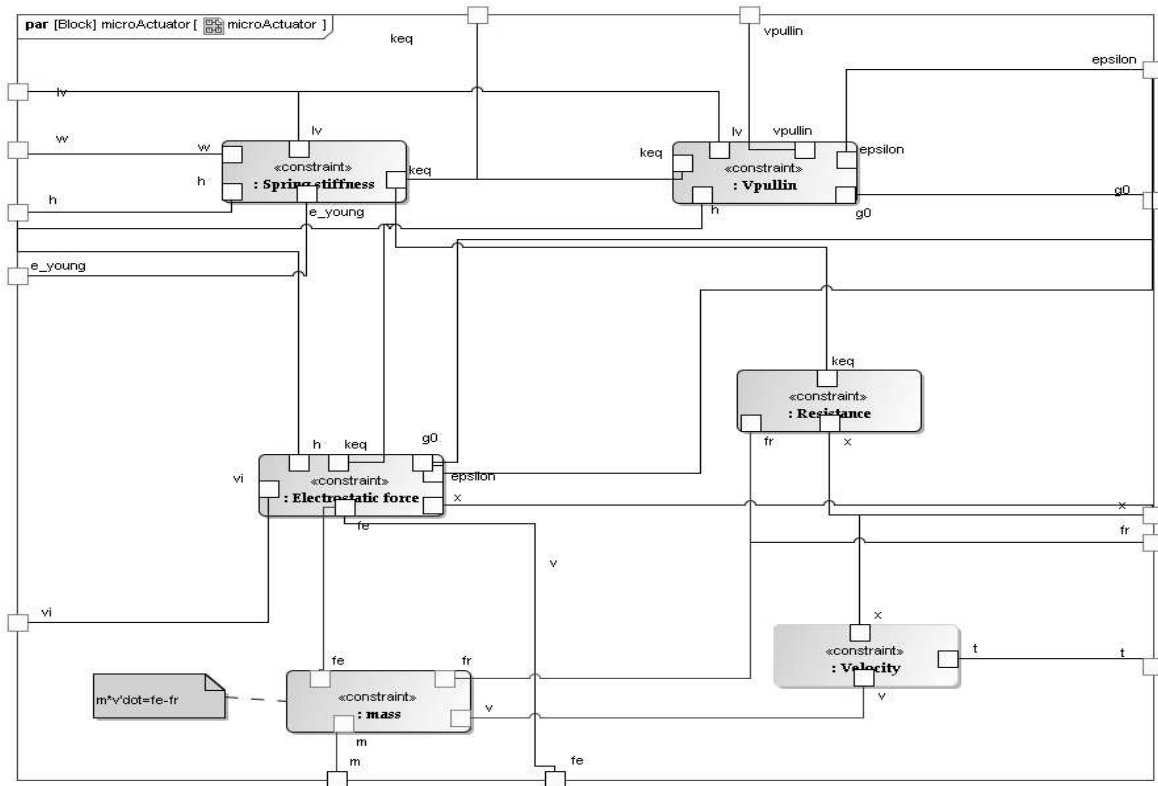

Figure 10. Parametric diagram of the microactuator block

be automatically parsed into specific analysis models.

A perspective is to establish links between *SysML* and tools and technologies for modeling used to represent or describe complex systems. In the field of complex systems, engineers and researchers often use *VHDL-AMS*. We plan to create the following links between *SysML* and *VHDL-AMS*:

- Generating *VHDL-AMS* code from *SysML* diagrams
- Extracting *SysML* diagrams from *VHDL-AMS* code
- Extending the *SysML* metamodel with *VHDL-AMS* characteristics.
